In, *Impact*, our second simulation type, students encountered two types of obstacles as they explored the haptic environment. The *Spheres* activity presented a stationary 8x8x8 lattice of spheres. Spaces among the spheres allow users to probe around and through the lattice, bumping into the spheres in the process. The second activity involving the simulation of impact is called *Bumped*. In this activity, the obstacle moves perpetually and repeatedly from left to right with a speed controlled by the researcher. The users feel being bumped by the obstacle when they explore the center of the haptic environment.

Methods

During the spring of 2010, we collected preliminary observational data in the form of video and field notes from 32 students (27 elementary and five undergraduate) interacting with the haptic activities. The students involved were chosen from three different populations within the Southcoast region of Massachusetts including local elementary schools, university freshmen and young children from a local urban city *Boys and Girls Club of America*. The observations occurred during informal interview sessions, where researchers asked questions to the students about what they thought and *felt* and how they related these experiences to the dynamic visuals on the screen. For undergraduate students, the interview sessions lasted about an hour; for elementary students, they lasted between 25-40 minutes. In this paper, we do not make a distinction among these students with respect to their developmental differences. Instead, we only provide a descriptive approach towards their haptic experiences to explore the features of their expressive discourse. Pseudonyms for student names are used.

We used the qualitative software product NVivo® to examine the use of expressive discourse. For example, we addressed the following: How did the student dialogue cohere with the expectations of the activity? What can we learn about the types of interview question and response patterns that inform future interface and activity design? We have used NVivo® to code for these types of expression as attributes for our particular cases (both students and activities). In order to answer the questions surrounding the activities' expectations the coded student discourse was cross-referenced with the set of expectations for each particular activity.

Our analysis of students' expressive discourse focused on how they could differentiate haptic experiences (e.g., "this felt like the ball was moving faster"). We initially identified three categories of expressive discourse. The first category is *metaphorical word use*. We define metaphorical word use as the set of utterances about objects or actions that are not present in the haptic-visual environment, but result from students' previous experiences. We further classified the use of metaphorical word use as scholastic (mathematical/scientific) or non-scholastic (non-mathematical/scientific). Scholastic use of metaphors relates objects or actions to mathematical or scientific objects students have previously interacted with. Non-scholastic use of metaphors is not related to mathematical/scientific objects but to students' everyday experiences.

The second category of expressive discourse is *reaction to sensual experiences.* We define a sensual experience as any form of expressivity that is a result of the students' sensations and reactions to the feedback (e.g., force, sound, or visual) they receive from the haptic device. We subdivided this category into descriptive aesthetics, evaluative aesthetics, and gesturing. Descriptive aesthetics pertains to utterances about the color, size, or feel of what students are seeing, feeling or hearing (Sinclair, 2004). Evaluative aesthetics differs from the descriptive aesthetics in that, instead of just describing the form (e.g. it's green), students are assigning some affective statement to their experiences (e.g. it's scary or it's beautiful). In addition to the verbal reactions pertaining to an activity's aesthetics, we also focused on students' sensual reactions through gesturing. We consider gesturing as a set of bodily movement for communicating in context, or collaboration with speech; either to oneself, a fellow student, or one of the interviewers.

The final category of expressive discourse is *developing a way of measuring and calibrating visual and physical spaces*. This corresponds to the students' routines as they attempt to measure and calibrate the physical and visual space during their haptic experience.

Results

Metaphorical Word Use

Examples of scholastic metaphorical word use were seen during an activity where students were presented a flat surface, which they could drop onto a small, white ball. When asked what would happen when the surface was dropped, one elementary school student (aged 8), Annie, predicted that it would fall to one side. This prompted another similarly aged student, Beatrice, to relate it to a "see-saw", and the white ball as the fulcrum. When asked to give a definition of fulcrum, Beatrice said "the center that keeps it together, like scissors". More metaphorical word use was seen with elementary school students during the *Break Through* activity. Students were presented with a barrier that provided resistance to passing through it, until enough force was exerted using the haptic stylus, thus releasing the resistance. As an explanation for this barrier, which some students described as a wall or "pressure", two groups of students reasoned that it had magnetic properties that "[didn't let] you go where you want". Undergraduate participants also used expressions containing mathematical metaphors. In one activity three undergraduates were shown a shallow, concave parabolic curve. The haptic stylus controlled a point displayed on the x-axis and, as they moved the point in the positive direction, students felt an increasing force, proportional to the parabola's slope, in the negative x-direction. In one student's explanation of this force-feedback, he referred to the feeling as "riding across sine waves".

The use of non-scholastic metaphorical word use, however, was more prevalent in our interviews. In one *Break Through* activity, when the force opposing user movement was activated, students described their movements as "heavier", "like rubber" or an "eraser on paper". In contrast, movements without the force were described as "lighter" or "freer". One student even compared their movements with, and without the force to being chased in a scary movie. The student related the opposing force to when they are walking and "you feel all that pressure, like someone's behind you, and you're scared". Movement without the force present represented a "relief" for the student.

Another metaphor discussed in a *Break Through* activity, related the force opposing movement to walking on a windy day. In the metaphor, the force was described by an elementary school student as "wind actually blowing you" towards the barrier. In a separate session, an undergraduate used the same metaphor, saying the force was like wind when you're walking, "there would be resistance to your movements." The *Bumped* activity also provided similarities between the elementary and undergraduate students. Two groups of students, one elementary and one undergraduate, described the periodic impacts as the beating or pumping of a heart, or a pulse. Along with the theme of periodicity, these two age groups also likened the period impact to a clock.

Reaction to Sensual Experiences

This type of expressive discourse classifies the communications of student reactions to sensual experiences during our activities. As an example, we again reference the force opposing movement in the *Break Through* activity. One student explained that when the force is not active the haptic environment "feels like it's empty", but with the force the environment has "something inside it." This explanation makes a description, in terms of a container, about the haptic sensation associated with moving through the environment.

The *Spheres* activity intends for students to describe how a lattice of spheres hindered or modified their movement within the haptic environment. During the interviews with both elementary and undergraduate students, movements across, and within the lattice were described as bumpy 20 times. Again, these "bumpy" descriptions pertain to student reactions to sensations caused by their movement through the environment.

Evaluative aesthetics differs from the descriptive brand, because students make affective statements rather than just talking about the forms of their sensual experiences. For example, in the *Break Through* activity, when one student pushed against the barrier he described it as "weird". When further evaluating the experience he said, "it feels like rubbing on rubber…it's weird." Some elementary school students exploring the spheres in the *Spheres* activity began to associate the colors of the spheres with how "hard" they felt. Interestingly, however, the stiffness of the spheres in the activity was identical. In the *Bumped* activity, one group of students indicated that the impact from the moving obstacle was emotionally affective. The students said that the unexpected impacts became "scary", because the sphere "just jumps out of nowhere".

In addition to the verbal reactions pertaining to an activity's aesthetics, students in our interviews also expressed their sensual reactions through gesturing. The *Bumped* activity provided a number of gestural reactions, mainly because it was the only activity offering objects that were out of the students' control. In each of our other activities, students were the initiators and producers of sensation on objects in the haptic environment. However, the students could not control the moving obstacle in *Bumped*. Therefore, students would make gestures to either avoid coming into contact with the obstacle, or seek out contact with it. This type of gesturing occurred when the obstacle was both invisible and visible.

In one interview, a student named Catie discovers that there is a different haptic sensation that results from pulling the device close to her body, rather than towards the base of the device. When the next student, David, begins using the device, Catie gets the attention of David and makes a gesture, pulling her arm towards her body, in an effort to show David the difference. While Catie makes the gesture, David mimics it, presumably in an attempt to achieve the same sensation as Catie.

One student, while moving through the *Bumped* activity used a gesture to test if they were causing the impacts or if the impacts were independent of their movement. While the student, Ethan, was moving the haptic device he noticed the device providing force-feedback. Ethan claims that he is not the source of the feedback, saying the device is "doing it on its own." Another student, Fred, questions Ethan by saying, "how do we know *you're* not touching it." In response, Ethan rests the haptic stylus in the palm of his hand, looks at Fred, and says, "see, I'm not doing it!" Fred appears to be satisfied with the evidence. This episode is quite significant because it illustrates a gesture powerful enough to convince another student that the sensation felt by Ethan was not caused by Ethan's movements.

Developing a way of measuring and calibrating visual and physical spaces

In some cases, fifth-grade students compared the regular structure of the lattice of spheres within the *Spheres* activity to familiar objects with regular structure. Students most often described the spheres as discrete objects, such as "bumps" or "rocks." As they explored, students also characterized the arrangement of the objects in space, starting with horizontal structure and then adding in a vertical component. One group offered, "it feels like you're going over bump after bump," noting repetition left to right. They later decided "it feels like stairs because it's going higher and higher," adding in the vertical. In this group, "stairs" became an accepted description adopted among the students and repeated: "like going down stairs," "like rocks piled up as stairs." Another group, that followed a similar pattern of describing horizontal and vertical structure, was more systematic in their investigations and specific in describing how the horizontal and vertical structure interrelated. Moving from left to right, a student sought to describe the repetition additively: "If I move one over, there's one more, and one more over there. Once you go over here, there's no more." This group also explored the vertical pattern in conjunction with the horizontal, using stairs as a way to describe change in two dimensions: "Every time I move down there's something stopping, and up, and sideways, kinda. […] As you go up, it stops, up, stop. [...] It's kinda like stairs, you stop it goes down, stop it goes down." This group also adopted "stairs" as one shared way to describe one aspect of the structure of the matrix.

The use of stairs to relate vertical and horizontal structure appeared during the non-visual portion of the *Spheres* activity. Once the students were shown the sphere lattice, one face of this three dimensional lattice was immediately revealed to them. The nature of flat computer monitors meant that the depth of the 3D model was obscured by the front of the lattice. But, students still noticed the depth in their explorations with the haptic stylus and in the visuals. In one third-grade group, Doug, Ellen and Fiona wondered aloud about the structure of this simulation in the depth dimension. By counting the visible spheres and using multiplication, Fiona decided that a face had 35 spheres (the proximity of the virtual camera to the lattice meant that some of the spheres were out of the field of view, and students counted a 5 x 7 lattice in the front face). As Ellen began to count the spheres by tapping them with the haptic stylus, Doug and Ellen agreed that the front face was not the entirety of the lattice. “35 is just the top.” They sought a way to complete the count in the depth dimension, which was more difficult to see on the screen. Ellen said, “You can't tell how many there are down, so you can't tell how many there are.” She went on to elaborate as she explored in the depth dimension: “If you, like, move it farther away and closer to the machine you can kind of feel the ones on the bottom, but not really.” The laptop screen was tilted away from her, and her descriptions appear to associate “down” with depth. As she continued to probe, they discussed how one might arrive at a full count of the spheres. “You would do 37, I mean 35 times how many there is down.” While Doug attempted to tell how many there were based on the shadows of the spheres in the display, Ellen began counting aloud. As she moved the stylus closer, and then farther away from herself she counted: “One, two, three, four...” When asked whether she was counting the spheres on the laptop screen, she said, “No. Feeling them.” It appeared that the desire to get a full count of the lattice and the difficulty of getting accurate visual confirmation led Ellen to count by feeling variation along one specific dimension. Communication among the students and the researchers during this activity involved both expressive word use and gesture, as Ellen used deliberate and exaggerated poking motions to illustrate her count while we all attended to her efforts.

Discussion

From the findings that relate the expectations of each activity and students’ expressive discourse, we formulated a set of haptic design principles. For example, activities that provide resistance in the form of a breakable wall (i.e. resistance against moving then, after a certain level of force is exerted, no resistance) are described by students as containing stoppages, “getting stuck” and preventing them from “going where you want”. We also discovered that students were able to discriminate varying levels of viscosity, when the viscosity change is preceded by a breaking point.

No visuals in an activity often led to students exploring positions within the haptic environment where they posited haptic sensations would occur. Student discourse also indicated that haptic sensations could incite affective statements. For example, when students encountered an object moving along a track, the frequency of impact led to unsettled emotions (e.g. “creepy”, “scared”, “losing control”).

The analysis also led to the identification of distracters in the activities, defined as any element of an activity (i.e. visual or haptic) that distracts the user from the design intentions of the activity. For example, in the *Falling Off* activity, students were more focused on the visible, squiggly lines on the surface instead of exploring the feeling of moving off the surface. Further, we found that students who worked within haptic activities more than once were engaged (i.e. attentive to the interview questions and activity tasks) throughout the 25-30 minute interview. In fact, some students were more active as their interaction with the haptic environment increased.

In creating haptic principles and identifying distracters, we have now discovered a set of haptic experiences that have been shown to be successful in eliciting certain student discourse. Using this knowledge, we are designing more mathematical haptic activities, in preparation for a main study during the spring of 2011.

Students' expressive discourse was particularly rich in their reaction to sensual experiences and use of metaphors. Students' genuine participation in the experience was reflected in their gestures and utterances of surprise, excitement, shock, etc. which provided a natural context in which they developed and tested self-generated hypotheses. The instances in which students shifted their everyday metaphors to scholastic (mathematical/scientific) ones made us wonder the characteristics of the contexts in which they moved between the informal and formal discourse during their experiences. Since our future goal is to use the haptics environment to develop and implement mathematical activities, adding a fourth category to our initial classification of expressive discourse seems necessary. The fourth category would mainly focus on how, and under what conditions, students move back and forth between everyday words to the more technical/formal, mathematical words. We are also interested in how students cope with the notions of variance and invariance as well as continuity and discreteness as they conjecture about mathematics through their haptic experiences in physical environments.

In summary, a new set of design principles emerged from our analysis of expressive discourse as we take steps towards making the haptics experience mathematically relevant and significant. We believe that students' self-motivated hypothesizing/theorizing through interaction with peers, as reflected by their discourse in our preliminary study, is crucial for mathematics learning. The haptics environment presents many opportunities to contribute to the teaching and learning of mathematics.

This paper reports on a mixed methods study of 111 AP calculus students' self-reports of their graphing calculator use, comfort, and rationale when choosing between mathematical solutions produced with and without a graphing calculator.

Graphing calculators have taken on an important role in learning mathematics, especially at the secondary level (Dion et al., 2001). Graphing calculators have been reported to have been used by over 80% of U.S. high school mathematics teachers and are currently allowed on more than 70% of the U.S. state's mandated standardized tests (Texas Instruments, 2010; Weiss, Banilower, & Smith, 2001). In addition, they are allowed on 100% of college entrance exams and AP calculus, statistics, physics, and chemistry exams (College Board, 2010). One way in which a graphing calculator is often promoted in the classroom is as a tool for checking or verifying work done by hand (e.g., Doerr & Zangor, 2000; Harskamp, Suhre, & van Streun, 2000; Hennesey, Fung, & Scanlon, 2001; McCulloch, 2005; 2009; Quesada & Maxwell, 1994). The fact that students use the tool to check their work is not surprising. However, the literature has not considered the benefits and constraints for students when using the tool in this way. In this paper we report on a mixed methods study of 111 high school Advanced Placement (AP) calculus students' uses of graphing calculators to check their work and their methods for reconciling any differences between solutions found by hand and with the technology.

Background

Graphing Calculator as a Checking Tool

Doerr and Zangor (2000) investigated the ways in which students use graphing calculators to support mathematical learning. They found that the graphing calculator was often used as a checking tool "when it was used to check conjectures made by students as they engaged with the problem investigations" (p. 156). Quesada and Maxwell (1994) used open-ended questions to analyze students' thoughts on the positive and negative aspects of the graphing calculator. They found that a majority of students felt that the ability of the graphing calculator to check answers was a positive aspect of the tool. From additional interviews with students, the researchers found,

> The statement 'the ability to check their answers' was interpreted by some to mean not only the capability of confirming graphically or numerically the answers obtained algebraically, but also the ability (new for many of them) of thinking graphically about problems before trying to solve them algebraically" (Quesada & Maxwell, 1994, p. 213).

Other researchers have observed the promotion and use of the graphing calculator as a checking or verification tool in the classroom (e.g. Berry, Graham, & Smith, 2006; Doerr & Zangor, 2000; McCulloch, 2009), and researchers have seen that the use of the tool in this way can be important for creating an understanding of graphing (Hennesey, Fung, and Scanlon, 2001), and for allowing students to support their analytical work with graphs and tables (e.g. Waits & Demana, 1994). Researchers have not yet, however, clearly determined why a student chooses to use the tool to check (Berry et al., 2006).

Confidence and the Graphing Calculator

Many students recognize the effectiveness of the calculator for confirming or checking the reasonableness of answers, but they struggle when answers obtained on the graphing calculator do not match their own expectations or work they have done on paper (Kenney, 2008; McCulloch, 2005; 2009). This relates to a level of confidence that students have both for their own work and for the graphing calculator as an effective tool in problem solving. Many researchers have been able to find improvements in assessment scores when students use graphing calculators (e.g., Ellington, 2003), and some have suggested that a possible reason for such improvements is that students are more comfortable or confident when they have a graphing calculator to use (Dunham, 2000). However, it seems that even when students feel that graphing calculators are useful, they may often lack confidence in the calculator's ability to help them in problem solving (Graham, Headlam, Honey, Sharp, & Smith, 2003) and may put more trust in their own work than in the calculator. In other cases, students' confidence in their mathematical ability contributes to a lack of perceived need for verification with the graphing calculator (Mesa, n.d.)

On the other hand, there is concern that students can become over-confident in the graphing calculator, using the device as a "black box" and blindly accepting calculator output (Doerr & Zangor, 2000; Forster & Taylor, 2000). Doerr and Zangor (2000) explain that this occurs when learners depend on calculators to produce answers without attending to the meaning, purpose, or interpretations of the problem situation. They found that this "black box" use results when neither the student nor the teacher provides meaningful strategies for calculator use. Similarly, Goos, Galbraith, Renshaw, and Geiger (2003) suggest the calculator can take on the role of "master" for the user and that students can become overly dependent on the tool when "lack of mathematical understanding prevents them from evaluating the accuracy of the output generated by the calculator" (p. 78). When used in these ways, the graphing calculator can become a source of mathematical authority for the user (Williams, 1993; Wilson & Krapfl, 1994) and be over-used to the point that students rely on the calculator with little critical analysis of the results (Burrill et al., 2002).

Research has not yet looked in detail at the level of confidence that students have for their own work or for the graphing calculator itself when using the tool in problem solving. In this study, we focus on this issue by examining where students place their trust when conflicts arise in problem solving with a graphing calculator. In this study, we address the research questions: What do students say they do when a solution produced without technology does not match one produced with technology? How do they say they reconcile this situation?

Methods

Data Sources

Advanced Placement (AP) Calculus classes were chosen as the focus for this study because the curriculum and expectation of calculator use is relatively consistent nationwide as it is set by The College Board. To ensure that the population of students was as diverse as possible, this study was set in four high schools in the northeastern United States. High School A is located in a low-income urban community, High School B serves students from both suburban and rural communities, High School C serves students in an affluent suburban community, and High School D serves students in a middle class suburban community. All four of these schools provide their AP Calculus students with a graphing calculator to use at home and at school. High Schools A, B, and D provided their students with a TI-83+, while High School C provides the TI-89 (which has Computer Algebra System (CAS) capabilities). For the purposes of this study, the term graphing calculator refers to both calculators.

All of the students at these four schools (n = 111; 49 female; 62 male) completed a survey instrument designed (based on pilot studies) to identify the ways that they typically use a graphing calculator, both in and out of the classroom, and their comfort in doing so. In particular, the survey provided data on student demographics, mathematical achievement as determined by their math teacher, frequency of graphing calculator use and comfort with the tool. In addition, an open ended item was included that read:

> *Imagine the following situation: You solved a problem on your own and then used your graphing calculator to check your solution. The calculator gave you a different solution than the one you got when you worked the problem on your own. Which answer do you trust? Why?*

All 111 respondents provided answers to this question on the survey, in many cases surprising the researchers with the amount of detail included in their responses. The responses to this open-ended item are the focus of this paper.

Data Analysis

All categorical data from the survey instrument were entered into an Excel file and each written response to the open-ended item above was first coded for solution chosen in the reconciliation process (i.e. graphing calculator (GC), non-graphing calculator (non-GC), or neither). We then examined all possible associations between descriptive student characteristics and solution chosen. Since the descriptive data were categorical in nature, a chi-squared test for association was used. Associations were examined between solution choice and each of gender, teacher, teacher-rated mathematics ability, and student-reported comfort using a graphing calculator. Next, we analyzed the written responses to the open-ended item using a thematic content analysis process (Coffey & Atkinson, 1996). After coding each response based on the solution ultimately chosen in the reconciliation process, we examined students' written responses for emerging themes within each solution group. This resulted in the development of a codebook with 12 data-driven codes. The codes that emerged within each group of solution choices (GC, non-GC and neither) directly corresponded with each other, regardless of the ultimate solution choice, and fell into four larger categories. Our resulting list of these four categories appears in Table 1 below. It is important to note that the assignment of codes to student responses were not discrete. For example, the response "If I'm not sure, the calculator. If I'm sure, my answer. I probably plugged something wrong into the calc," was coded as both confidence in math ability and careless errors. In the next section, we provide further details and interpretations for the coding results.

Table 1

Categories for rationale of solution choice

Category	Definition
Careless errors	Student notes that "careless errors" (either arithmetic or syntactical) are possibly the cause of any discrepancies between GC and non-GC solutions.
Check work	Student notes that either the GC or non-GC (or both) solution(s) must be checked for small errors and, barring any small errors, ultimately accepted.
Recognition of GC affordances and limitations	Student notes either affordances or limitations of the GC in their reasons for accepting or rejecting a GC solution.
Confidence in math ability	Student notes acceptance or rejection of a GC solution is based on confidence (or lack there of) in own math ability.

Given the situation posed in the item, that of having to reconcile a GC produced solution with a different non-GC produced solution, 60 out of 111 students (54%) wrote that they would ultimately choose a GC produced solution, 39 (35%) said they would choose their own work (non-GC produced solution), and 12 (11%) did not make a definitive choice between the two (Figure 1). No associations were found between the solution choice and gender $(X^2(2, N=111)=2.649, p=.266)$, teacher $(X^2(6, N=111)=8.231, p=.222)$, teacher rated mathematics ability $(X^2(4, N=11)=2.603, p=.626)$, or student reported comfort using a graphing calculator $(X^2(4, N=111)=4.051, p=.399)$. The most commonly provided explanations for deciding what to trust, regardless of solution choice, were students' concerns about making *careless errors* (n = 58, 52%) and students' suggestions that they would *check their work* before choosing which solution they trust (n = 43, 38%). A summary of the frequency of codes within each solution category appears in Table 2 below.

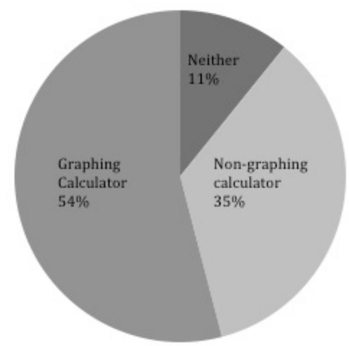

Figure 1: Student solution choices

Table 2

Code frequency in each solution preference category

	GC solution	Non-GC solution	Neither	Total
Careless errors	36	18	4	58
Check work	22	14	7	43
Recognition of GC affordances and limitations	13	6	1	20
Confidence in math ability	5	6	1	12

Note: Codes are not discrete

The following sections report a more detailed look at these findings. We have sorted the findings by the three choices made by students – GC solution, non-GC calculator solution, and neither – and include at least two examples of students' statements as they relate to the categories of rational identified.

Trust the Graphing Calculator Solution

Careless Errors

As noted above, 54% of the students responded that they would choose a GC produced solution over a non-GC produced one. More than half of these students' reasoned that they would choose the GC solution because it is easy to make careless errors when working by hand. The following statements by students in this category exemplify their responses:

- "I would trust the calculator because it is easy to make a careless mistake in computation when without a calculator and the numbers are large."
- "The calculator as long as I am entering it correctly because I have a greater margin of error than does the calculator."
- "I trust the calculator because of human error."

Students not only recognized that careless errors by hand were likely, but some (n = 6) also noted that they would use the situation to help identify their errors (e.g. "I would trust the calculator because everyone makes mistakes, so I would use that proposed answer and work back and see my mistake and fix it"). On the other extreme, a few students noted that they trust their calculator solutions so much that they would change their written work to match it. For example, one student wrote, "Calculator. I am a very confident calculator user. I'd try to change my work to match the calculator answer."

Check Work

Not all of the students automatically identified the GC solution as the one they would trust. Sixteen students noted that they would first check their work, both written and GC produced, before choosing the GC solution. The following responses are examples of this:

- "I would double check my work and also how I entered the problem into the calculator. If they still don't match, I would trust the calculator's answer."
- "Well I would actually make sure I plugged in everything correctly into the calculator. If that was right, then I would doubt my own solution. So I'd trust the calculator answer."

Although these responses might imply a similar feeling to those in the careless error category, we see these students' willingness to check all work first as demonstrating more than just blind trust in the technology.

Recognition of GC Affordances

Justification for choosing a GC produced solution was also attributed to a belief in the infallibility of the GC by 13 students. This reasoning was evident in responses such as:

- "Calculator – we can make math errors but the calculator doesn't."
- "Unlike humans, calculators don't make computational mistakes for no apparent reason."
- "Calculator. The only possible error made by a calculator occurs when a wrong number, equation, etc. is entered. Room for error on the calculator is restricted."

We have identified this reasoning under the broader category of limitations and affordances of the graphing calculator due to students' beliefs that one of the affordances of the calculator is that it does not make errors.

Confidence in Math Ability

Five of the 60 students reported that they trusted the GC due to a lack of confidence in their own mathematics abilities. For example, students answered:

- “Calculator, I have no confidence in my math abilities.
- “I would trust the calculator because I am usually wrong and I have had success in the past with trusting the calculator.”
- “The calculator. It is better at algebra than me.”

Interestingly, only one of the students in this category was rated as a relatively lower ability student by the teacher, one other was rated average, and the other three were considered to be among the strong students according to the teacher. Thus, student responses show a disconnect between their confidence in their ability to do mathematics and their actual performance in class.

Trust the Non-Graphing Calculator Solution

Careless Errors

Thirty-five percent of the calculus students reported that they would choose a non-GC produced solution in the situation that it did not match a GC produced one. Like those that chose GC produced solutions, many in the non-GC category also considered the possibility of careless errors when making their decisions (n=17). The difference, however, was that these students were not as concerned about errors in their written work as they were about errors they may make pressing the calculator buttons. For example, students suggested:

- “I probably entered it incorrectly on the calculator. I’d try to punch it in again.”
- “My own answer is probably right; I have finger-calculator problems. Usually the reason for the disparity between my value and the calculator value is the lack of parentheses or wrong decimal place.”

Unlike the GC choosers, none of these non-GC students who used the careless error reasoning suggested using the situation to help identify their errors. They were not as concerned with determining how to get the correct solution on the calculator if they trusted the work they had done by hand.

Check Work

Thirteen of the non-GC choosers responded that they would trust their non-GC produced solution after checking their work for mistakes. For example, students stated:

- “I’ll check my work again and if I didn’t do anything wrong then I’ll trust my work.”
- “I would double check my work, and then use my answer because I could have easily input something wrong in the calculator.”

As with the GC group, these students were not willing to blindly accept one answer over the other, but did demonstrate more confidence in their own work. Many of the reasons in both this and the careless error category were related primarily to students’ personal experiences, as evidenced by their discussions of what they “often,” “easily,” or “usually” do.

Recognition of GC Affordances

Like the GC choosers, non-GC solution choosers noted confidence in their mathematical abilities or their beliefs about the affordances or constraints of the GC in their justifications. However, unlike the GC produced solution choosers, these students placed the authority in the situation with themselves. For example, six responses for the non-GC choosers focused on the limitations of the GC as a reason for not trusting its solution. Students shared:

- “I trust the answer I would have gotten on my own. The calculator does not show all the steps and it is easy to make mistakes when putting information into the calculator.”
- “I trust my own, sometimes the graphing calculator comes up with weird answers using trig functions or does not find the right answer.”

- "I would trust myself because the calculator tends to make mistakes sometimes in graphing when the equation isn't entered properly."

It is interesting to note in the last two examples that students place the blame for mistakes on the calculator, when in fact mistakes may be a result of their own careless errors. We placed them in this category, however, based on the students perceptions of the tool, not our own.

Confidence in Math Ability

Six students noted their *confidence in their mathematical abilities* (rather than their lack of confidence) as their reasons for trusting the non-GC solution. Responses included:

- "As long as I am confident with the answer I got, and was not very unsure with it in the first place, then I would trust my own answer not the calculator's."
- "Myself, because I am able to do the problem on my own, I wouldn't even need to use the calculator."

It is important to note that none of the students who noted confidence in their mathematical abilities as justification for choosing a non-GC produced solution were considered by their teacher to be among the highest ability students as compared to their peers.

Trust neither solution

Twelve of the 111 students that participated in the study did not make a definitive choice between either the GC or non-GC produced solutions. The responses of these students indicate that they do not necessarily value or rely on one solution over the other. Instead, they all noted the importance of rechecking their work, on both the GC and paper, to identify errors and to understand why the solutions differed. For example,

- "I recheck the calculator first and then my own answer. I check both and trust neither."
- "I don't trust either until I figure out where the mistake is. I either made a mistake with the math or I typed something into the calculator wrong. When the answers match, I trust the answer."

Again, these students appear to be considering the same things as the GC and non-GC choosers (i.e. checking their work and the possibility of careless errors on paper and in button pushing), however they place equal value with each method. Most importantly, they do not exhibit blind trust in either solution method. However, the responses do suggest that, as long as the two solutions do match, students would feel confident with the answer.

Discussion

Our findings in this study show that, whether they would choose the GC or non-GC solution when a conflict in answers arises, students are considering similar factors:

- The possibility of careless errors
- The importance of checking their work
- The constraints and/or affordances of the graphing calculator
- Confidence in their mathematical abilities

More than half of the students chose the GC solution over the non-GC produced solution. Many of the students' reasons for doing so were attributed to lack of confidence in their mathematical ability or to an over confidence in the infallibility of the GC. This finding is consistent with Goos et al. (2003) who found that students sometimes develop relationships with graphing calculators in which the graphing calculator is viewed as the "master". This suggests that it is truly important for teachers to be aware of the issue of mathematical authority. The students surveyed here are high school calculus students – often the best and brightest at their schools – and we find that more than half of them are handing the authority in a mathematical situation to the tool over themselves. This raises concerns for the results we might find with a group of less strong students.

On the other hand, the large number of students that noted they would choose the GC because they are concerned about making careless errors in their written work gives credence to the literature that has suggested that students attitudes towards mathematics increases when GC's are available because having the tool increases their levels of confidence (e.g. Dunham, 2000). If having a GC available can decrease students' concerns about the occurrence of careless errors, it is possible that students may spend less time worrying about small mistakes and more time focusing on thinking deeply about the mathematics.

It is promising to see that more than half of the students, regardless of solution choice, noted the need to check their work. This suggests that these students are thinking critically about what might have caused the difference in answers, rather than just accepting one as true. On the other hand, it is possible that those students who did not mention checking might have assumed that the situation was placed in a testing situation, one in which they may have assumed they would not have time to go back and check their work and would thus be forced to choose a solution and move on. Such interpretations should be examined more carefully in future studies.

In conclusion, given the prevalence of graphing calculator use in U.S. high school classrooms and standardized tests, these tools are likely going to be a mainstay in school mathematics for quite some time (Weiss, Banilower, & Smith, 2001; Texas Instruments, 2010; College Board, 2010). The results of this study suggest that while such promotion may be beneficial, it needs to be handled carefully so that students do not blindly place mathematical authority with the tool when reconciling differing solutions. To build a better understanding of these phenomena, further research is needed on how graphing calculator use and decision making is being promoted by teachers as well as how students perceive this promotion. In addition, it is important to investigate if these results hold true for other technology tools such as computer algebra systems, spreadsheets, and dynamic geometry systems.

A COMPARISON OF MIDDLE SCHOOL STUDENTS' ARGUMENTS CREATED WHILE WORKING IN TECHNOLOGICAL AND NON-TECHNOLOGICAL ENVIRONMENTS

Ryan C. Smith
University of Georgia
smithryc@uga.edu

This study characterized and compared the arguments eighth grade mathematics students created while working in technological and non-technological environments. Toulmin's (1958/2003) argumentation model was used to analyze the content and structure of the arguments, including the ways in which the students used the tools (technological and non-technological). Students in both classes were less likely to make their reasoning explicit when using tools, technological or non-technological, which may be related to the task on which the students were working and the use of the tools as a visual referent.

Background

The development of mathematical reasoning and understanding are culturally mediated, through language and through the use of tools (Lave & Wenger, 1991; Vygotsky, 1978). From this socio-cultural perspective, there is a strong connection between students' uses of tools and their learning because tools are the instruments of access to the knowledge, activities, and practices of a classroom community (Lave & Wenger, 1991). Productive activity with the tools and the understanding of them are not separate. Verillon and Rabardel (1995) indicate that tools do not exist as tools until the user is able "to appropriate it for himself and has integrated it with his activity" (p. 84). The use of tools and understanding their significance interact to become a single learning process.

In mathematics classrooms, tools are frequently used. Traditional tools such as compass, straight-edge, ruler, and scale have been used for thousands of years to explore, conjecture, and make meaning of mathematics, especially geometry. With the advent of the microprocessor, technology tools have become more prevalently used in the mathematics classroom. One type of technology tool that has become popular in the teaching and learning of geometry are dynamic geometry environments (DGEs), such as The Geometer's Sketchpad (Jackiw, 2001). Many teachers, researchers, and professional organizations have suggested the use of dynamic geometry environments to teach geometry (e.g. NCTM, 2000).

The use of tools is an important aspect of participating in a community of practice. Similarly, the use of language plays an important role for an individual to participate in the community. Although it is important for individuals to learn from the discussions of other members of the community, it is even more important to learn how to speak in the community of practice (Lave & Wenger, 1991). The affordances of the tools dictate the understandings that one can construct within the community and, in turn, the understandings that can be developed by the classroom community. Thus, the discourse of the classroom, which includes argumentation, is based, in part, on the use of tools. As technological tools become more prevalently used in the classroom, in what ways does the content and structure of the arguments students create differ when using technological and non-technological tools? The purpose of this study is to describe the arguments created by students enrolled in two eighth grade mathematics classes, one in which the students regularly use a DGE and one in which the students use non-technological tools, and compare the content and structure of the arguments created by pairs of students in each class.

One model that has been used by several researchers (e.g., Hollebrands, Conner, & Smith, 2010; Lavy, 2006; Stephan & Rasmussen, 2002) in mathematics education to examine students' mathematical arguments is Toulmin's model of argumentation (Toulmin, 1958/2003). Toulmin decomposed an argument into six components: claim (the conclusion whose validity is being established), data (the facts being appealed to as the foundation of the claim), warrant (the link between the data and the claim), backing (circumstances in which the warrant would otherwise be invalid), qualifier (confers the strength of the warrant), and rebuttal (circumstances in which the warrant does not hold). Figure 1 shows how these six components (data, claim, warrant, backing, qualifier, and rebuttal) fit together. Data is provided or constructed and "so" a claim is made based on this data. This claim can be made based on this data "since" the warrant. The warrant is relevant "on account" of the backing. The claim is valid "unless" the rebuttal occurs.

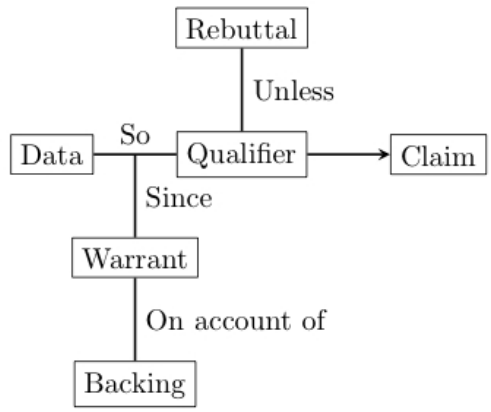

Figure 1. Toulmin's (1958/2003) Model of Argumentation

Methods

For this study, two classes of eighth grade students were selected to participate in a two-week classroom teaching-experiment on triangles taught by the author. I conducted the study with students of varying ethnicities and socio-economic status at an urban public middle school in the southeast United States. For one of the classes, technology played an integral role. Students used a dynamic geometry environment, The Geometer's Sketchpad (Jackiw, 2001), to explore and investigate geometric concepts. The majority of the tasks developed for this unit utilized this technology. For the other class, the students used traditional mathematical tools such as scissors, rulers, compasses, protractors, and snap-cubes. For both classes, the tools provided students with a means to reason and develop new understandings about the geometry concepts. In order to minimize the amount of variation between the two classes, the selection and sequence of tasks for each class were similar. Furthermore, the design and implementation of the majority of the tasks and activities for both classes were similar in nature with the major difference being the tools available to the students. In some instances, the tasks differed to capitalize on the affordances of the tools.

During the study, the students in both classes were placed in pairs. By having the students work in pairs, the students were given the opportunity to have discussions with their partners while working on the tasks. These discussions were the primary focus of the study's analysis. I chose to use pairs rather than larger groups to maximize the opportunities for students to interact with the mathematical task while still having peer-to-peer discourse. Four pairs from each class were purposefully selected to be the focus of the data collection and three pairs were selected for analysis based on the students' attendance. To select the pairings, I asked the regular classroom teacher to identify students that would be willing to verbalize their thinking and work well together. The pairs of students used in the analysis from the technology class were Amy and Judy; David and Erica; and, Heather and Mary[1]. The pairs of students from the non-technology class were Andy and Frank, Bob and Ellen; and, Clair and Jim[1].

Data collection consisted of: video and audio recordings of the two classes both small group and whole class discussions; video-recordings of the computer screen to capture the students' uses of technology; and, artifacts which include copies of students' written work including in-class work, homework, quizzes, and exams. Of each class's eight class meetings, the researcher only analyzed the small group and whole-class discussion for three tasks, although results from the analysis of one task, the triangle inequality, will be presented in this paper. I transcribed the video recordings of the whole class discussions and small group discussions. From these transcriptions, reasoning episodes were established by identifying claims. I then created a description of the argumentation episodes for that claim which included the participants' words (from the transcripts) and actions including the students' uses of the mathematical tools. Then, I diagrammed the argument according to the model developed by Toulmin (1958/2003) including each of the six constructs, data, claim, warrant, backing, qualifier, and rebuttal. For a given argument, some of these components were not specified and I had to make some inferences. In these cases, I noted these inferences and attributed them to a student, the teacher, or a combination of students and/or teacher. In the diagrams, I used a box to outline each of the spoken or known constructs. If I made an inference, I used a "cloud" to note the inference in the diagram.

Results

The results reported in this paper are based on data taken from tasks in which the instructional goal was for the students to develop an understanding of the triangle inequality theorem. The students in the technology class used a pre-constructed sketch to explore whether given sets of segments would form a triangle. The sketch allowed the students to adjust the lengths of the segments using sliders and to drag the segments without changing their lengths. The students in the non-technology class completed the same task using snap-cubes and rulers. While working on the triangle inequality tasks, the three pairs of students from both classes created arguments of various structures and contents. Three themes emerge in the comparison of the content and structure of arguments: the difference in the number of arguments between the two classes and the frequency in the use of the technology/tools; the explicitness of the warrants and the use of technology/tools; and, the content of the additional data.

The Number of Arguments and the Frequency in the Use of Technology/Tools.

The first theme to emerge in the analysis of the arguments is the difference in the number of arguments created by the pairs of students in each class. The pairs of students working in the technological environment created 75 arguments. In comparison, the pairs of students working in the non-technological environment created 56 arguments. This difference is even greater considering the students in the non-technology class had twenty additional minutes of class time to create arguments when they were asked to compare their answers to exercises on the homework with their partners. Removing these arguments, the students in the non-technological class only created 44 arguments. In addition to the discrepancy in the number of arguments, there was also a difference in the proportion of arguments in which the students used the technology/tools.

While working on the triangle inequality task, the pairs of students in the technology class employed the technology in 59 (79%) of their arguments. The pairs of students in the non-technology class created 19 (34%) arguments in which they used the tools. The higher proportion of arguments in which the pairs of students employed technology is most likely due to its use during the opening activity. During this activity, the teacher did not intend for the students to use the technology. However, the students requested to use it to assist them in solving the problems. The students in the non-technology class did not request to use the snap-cubes during a similar opening activity. At times, the pairs of students in the non-technology class used a ruler to make a sketch, but this was infrequent. Perhaps, the students in the technology class viewed the technology as a tool that can assist them in solving problems. The students in the non-technology class may not have viewed the snap-cubes in this manner. Rather, the students may have seen the snap-cubes as a means to create data to make a generalization, but not to solve problems.

The Explicitness of the Warrants and the Use of Technology/Tools

Although the pairs of students in the technology class created more arguments, the content and structure of the arguments in relation to the use of tools, both technological and non-technological, were similar for both classes. When working on the triangle inequality tasks, the pairs of students in both classes were more likely to provide an explicit warrant when not actively using the technology/tools than when the pairs of students created an argument using the technology/tool.

Arguments created by the pairs of students working in the technological environment. Of the 59 arguments in which the pairs of students in the technology class employed technology, they only provided an explicit warrant for 6 (10%) of these arguments. Of the 16 arguments in which technology was not actively employed, the pairs of students provided an explicit warrant for 12 (75%) of these arguments. The explicitness of the warrants may be related to the type of tasks on which the students were working. In general, when the students were using the technology, they were merely attempting to determine whether a triangle could be formed with a set of segments. For example, Judy and Amy attempted to determine whether a triangle could be formed with segments of lengths 3, 4, and 4. Amy adjusted the sliders accordingly and dragged the endpoints of the diagram to form a triangle. Judy claimed that a triangle can be formed by stating, "Possible" and Amy agreed by stating, "Yep." This argument is illustrated in Figure 2a.

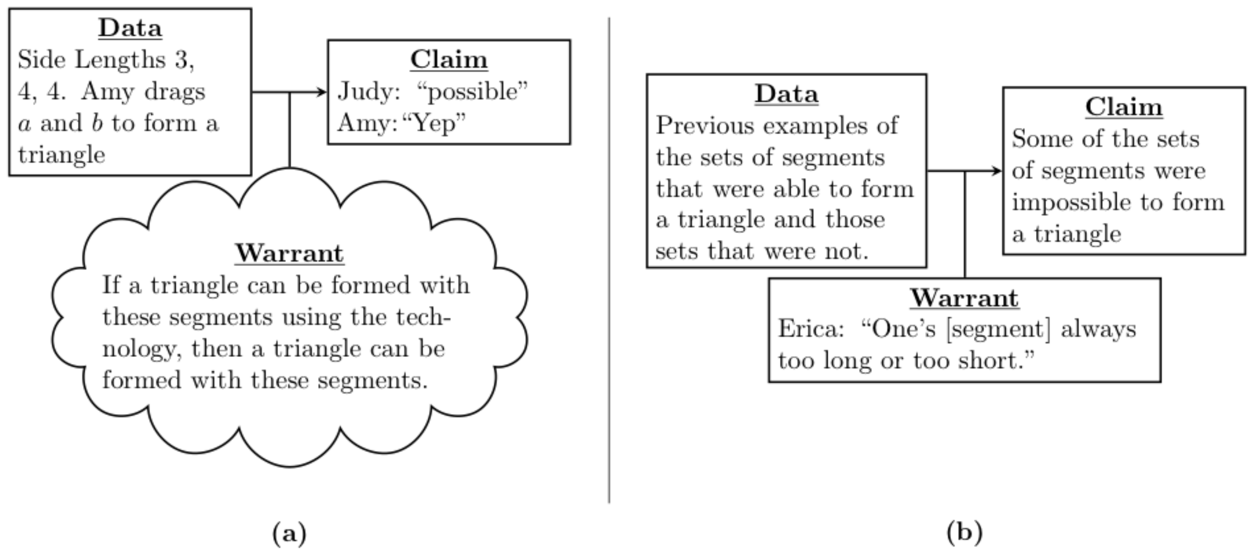

Figure 2. Arguments in which (a) students use technology and provide an implicit warrant and (b) students do not use technology and provide an explicit warrant

However, when the pairs of students were not actively using technology, the students were mainly working on generalization type tasks. For example, one of the arguments common to all pairs of students in structure was in response to the question on the task sheet, "Why was it impossible to construct a triangle with some of the given lengths?" One student, Erica, stated, "One's [segment] too long or too short." This argument is illustrated in Figure 2b. The question asked the students to generalize across the examples. The data used by the pairs of students to support their claims were their answers to the examples sets of segments on their task sheet. To gather this data, the students used technology. However, when responding to this question, the data had been previously collected and their reasoning was not based on their active use of technology, but on the product of their previous uses.

Arguments created by the pairs of students working in the non-technological environment. The arguments created by the pairs of students in the non-technology class were similar in content and structure with regards to the use of the non-technological tools and the explicitness of the warrant. Of the 19 arguments in which the pairs of students used the tools, they only provided an explicit warrant for 1 (5%) of these arguments. Of the 37 arguments in which tools were not actively employed, the pairs of students provided an explicit warrant for 30 (81%) of these arguments.

Similar to the pairs of students in the technology class, when the pairs of students were using the tools, they were attempting to determine whether a triangle could be formed. In these arguments, the data were the lengths of the segments; the arranging of the snap-cube segments; and, the appearance of the figures the students formed using the snap-cube segments. In one argumentation episode, Clair and Jim were determining whether a triangle could be formed with segments of length 3, 4, and 4. Clair arranged the snap-cube segments and was able to form a triangle. Jim said, "Possible." Clair agreed saying, "Yep." This argument is illustrated in Figure 3a.

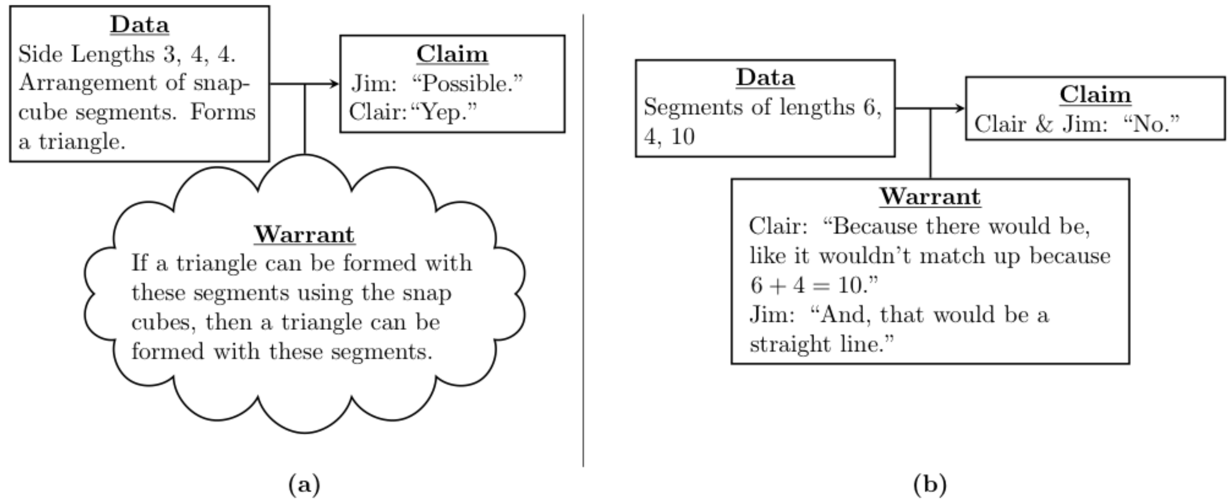

Figure 3. Arguments in which (a) students use non-technological tools and provide an implicit warrant and (b) students do not use tools and provide an explicit warrant

When not actively using the tools in the creation of their arguments, the pairs of students were generally working on generalization tasks and the majority of their warrants were explicit. However, the pairs also created arguments with an explicit warrant that was based on their previous uses of the non-technological tools. For example, Clair and Jim created an argument of this structure as they discuss their solutions to a homework problem. The problem asked the students to determine whether a triangle can be formed with segments of lengths 6, 4, and 10. Clair said, "The first one you said no and I agreed. I said no because there would be like it wouldn't match up because 6+4=10." Jim added, "And that would be a straight line." This argument is illustrated in Figure 3b. Although, in this example, the claim created by pair of students was not a generalization, they justified their claim by using a known theorem and stated what would occur if they attempted to form a triangle with segments of the given lengths.

Additional Data Collection

Many times the pairs of students in both classes collected additional data to verify or refute a previous claim. All three pairs of students in both classes created arguments of this structure. The students' decision to seek additional data may be due to a number of factors including an explicit challenge to a claim, the uncertainty of a claim, the uncertainty of a claim due to the lack of precision in the use of the technological tool, and the ways in which the students used the technology to collect the initial data. Even though the pairs of students collected additional data for a variety of reasons, the students in the technology class always used technology to collect this additional data, usually using the drag feature of the technology. For example, Amy and Judy were determining whether segments of lengths 2, 7, and 4 would form a triangle. Amy dragged the sliders accordingly and Judy claimed, "That looks totally impossible, that is huge." Amy immediately responded, "You don't know that though; that's the only thing." Judy agreed with the sentiment and stated, "I know, the weirdest looking stuff may be possible." Amy dragged the endpoints and is unable to form a triangle. She stated, "It's impossible." This argument is illustrated in Figure 4. In this argument, Amy challenged Judy's claim indicating appearances can be deceiving. Judy agreed and the pair of students sought additional data to verify or refute that claim.

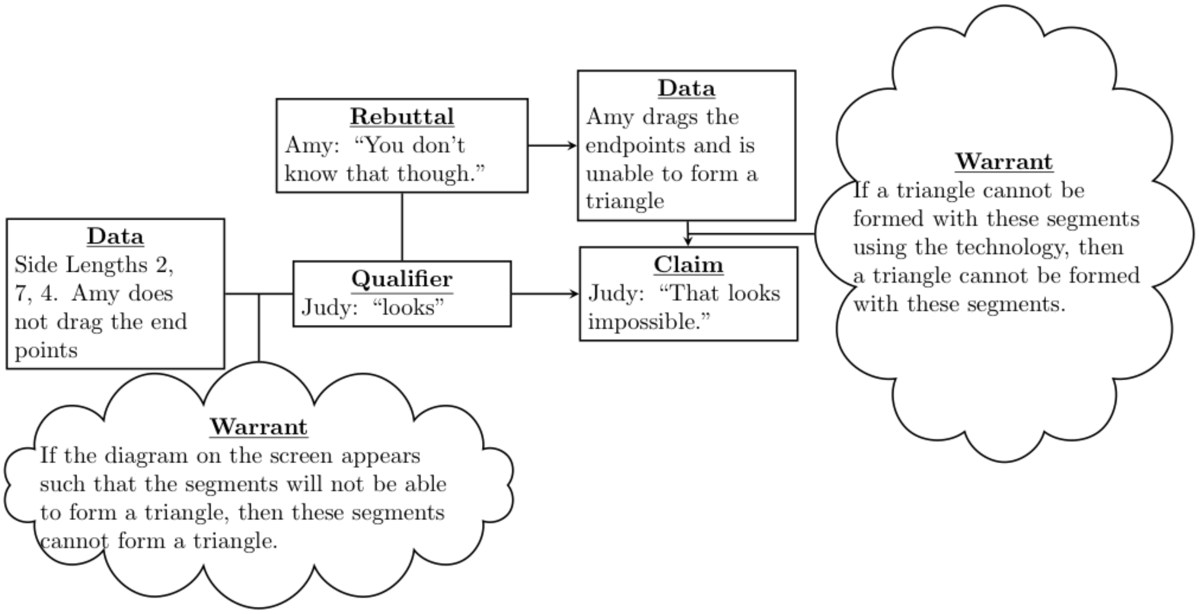

Figure 4. An argument in which additional data is collected using technology.

For the majority of the arguments in which the pairs of students in the non-technology class collected additional data, the students used tools by rearranging the snap-cube segments to determine whether a triangle could be formed, using a ruler to create a sketch to determine if a triangle could be formed, or focusing on different features of the tools. Although the pairs of students mainly used the tools to collect additional data, this was not always the case. At times, the students used known facts such as definitions and theorem as additional data to verify or refute a claim. For example, Ellen had written on her paper that a triangle could be formed with segments of lengths 10, 7, 24. The teacher asked her, "So, you think 24?" She responded, "As long as it's more than 17, it don't [sic] matter." Then, the teacher simply stated, "So 10, 7, 24…okay, okay." Ellen asked, "Hold on is it more or less?" The teacher pointed to the board and asked, "What does it say up there?" Written on the board was the triangle inequality theorem. Ellen began erasing her paper and changed her answer. Ellen collected additional data by reading the theorem on the board. Realizing that her initial claim was incorrect she made a new claim.

In the first example of this section, Amy challenged Judy's claim regarding the appearance of the diagram, which prompted the pair to collect additional data by dragging the figure to determine if the initial claim was correct. Perhaps, when these students' initial claims were challenged, the students felt the need to collect additional data using tools to verify their claims. In the second example, Ellen's uncertainty of her claim prompted her to question the basis for her reasoning and sought additional data to determine whether her reasoning was correct and, hence, whether her claim was valid. In other words, when a claim is challenged, the students used tools to collect additional data in order to resolve the challenge. When the students were uncertain about their claim, they collected additional data, either using tools or definitions and theorems, to determine whether they were using sound reasoning.

Discussion

One major finding of this study is when students actively used the technological or non-technological tools, they were more likely to create arguments with non-explicit warrants. In contrast, when the students did not actively use the tools, they were more likely to create arguments with an explicit warrant. Hollebrands, Conner, and Smith (2010) had similar findings in their study of the arguments college geometry students created when working with technology. When the college geometry students provided explicit warrants for their claims, the students were generally not using technology. The authors attributed this finding to the students' prior experiences in learning mathematics at the collegiate level where the students were expected to provide formal proofs, which require explicit warrants. This same attribution cannot be made to the middle school students in this study because it is unlikely they had been exposed to formal proofs. Rather, the lack of explicit warrants when the pairs of students were using the technological and non-technological tools may be attributed to the visual nature of the tools and the task on which the students were working.

The students' lack of explicit warrants in their arguments created while actively using the technological and non-technological tools may be related to the visual nature of the tools. Each student did not have his or her own personal set of tools. Rather, the pairs of students shared the tools and would alternate between using them. Thus, the students shared the same visual display presented by the students' uses of the tools (the screen for the students in the technology class and the arrangement of the snap-cube segments for the students in the non-technology class). Because the pairs of students had the same visual referent, they may not have been compelled to provide an explicit warrant. Lavy (2006) investigated the types of arguments middle school students created while using an interactive computerized environment. The author found that the students not only used images on the screen and commands as data, but also in their reasoning. Lavy concluded, "In a visualized environment, it is obvious that visual evidences can serve as reasoning in an argument, since all the work in this setting has the same character" (p. 168). Thus, the pairs of student may not have been compelled to provide an explicit warrant because they felt their reasoning was obvious to each other. In fact, when the students' challenged each other's claims the students generally used the tools to collect additional data rather than make their reasoning explicit (see Amy and Judy's argument illustrated in Figure 4).

In general, when the students were using the technological or non-technological tools, they were determining whether given sets of segment lengths would form a triangle. However, when the pairs of students were not actively using the tools, the students were mainly working on generalization type tasks. Even though the students in the current study did not actively use the tools when working on generalization type tasks, other researchers (e.g. Healy & Hoyles, 2001) found that students will create generalizations while using technology. Some pairs of students in Healy and Hoyle's (2001) study used a DGE to investigate relationships among the angle bisectors of a quadrilateral. The pairs of students did not create the same constructions and did not arrive at the same conclusions. However, those students that were successful were able to construct and measure aspects of their diagrams and developed generalizations while using the DGE. The students in the current study did not have the option of creating their own diagram. Instead, the students in the current study used a teacher-generated pre-constructed sketch that limited the students in how they could modify and/or measure aspects of the diagram. Perhaps, the students in the current study would have been more likely to use the technology while working on generalization type tasks if they had been given the opportunity to create their own diagrams.

DESIGNED AND EMERGENT PEDAGOGICAL SUPPORTS FOR COORDINATING QUANTITATIVE AND AGENT-BASED DESCRIPTIONS OF COMPLEX DYNAMIC SYSTEMS

Michelle Hoda Wilkerson-Jerde
Tufts University
Michelle.wilkerson@tufts.edu

Uri Wilensky
Northwestern University
uri@northwestern.edu

Often, quantitative and mathematical models are used to study complex dynamic systems–where collections of individual components interact to produce an emergent pattern of behavior. To interpret such models involves 'unpacking' the collective behaviors and interactions that underlie a given pattern. We investigate what representational supports in a technology-mediated agent-based modeling environment led secondary students to question and investigate the relationship between individual behaviors and collective patterns in a population dynamics unit. Our goals are to inform 1) our own design of educational tools and 2) the theoretical elaboration of general "conceptual leverage points" for mathematics and complex systems education.

Objectives / Purpose

Over the past several decades, there have been a number of technological and theoretical developments that have enabled scientists to explore the interconnected and complex nature of natural and social phenomena in ways that were not previously possible (Bar-Yam, 1997; Mitchell, 2009). This increasing capacity to document and study the world's complexity has led calls for complex systems topics and principles to be integrated into the K-16 curriculum (Forrester, 1994/2009; Jacobson & Wilensky, 2006; Kaput et al., 2005; Sabelli, 2006). Indeed, in her plenary session at PME-NA last year, English noted that technology and complexity "have led to significant changes in the forms of mathematical thinking that are required beyond the classroom" – and that technology has increased the demand for "the interpretation of data and communication of results" (2010, p. 33).

Our objective is to better understand how we can support students as they engage in one such "new" form of mathematical thinking – to interpret mathematical and quantitative models in terms of the complex, interactional events that they encapsulate and measure. This report is part of a larger design-based research project (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003) that seeks to (1) explore student reasoning about complex dynamic systems and associated mathematical ideas including the measurement and encapsulation of complex behavior, notions of rate of change and accumulation in multivariate systems, and nonlinearity; and (2) develop educational tools and activities that support such reasoning.

Background and Theoretical Framework

One important form of mathematical thinking related to complex systems involves understanding the relationship the behavior of a system at different *levels* (Wilensky & Reisman, 2006). Often, the relationships between the *individual* and *collective* levels of a system can seem inconsistent, since many individual behaviors and interactions underlie a given collective result – for example, individual cars in a traffic jam each move forward even as the jam itself propagates backward; and chemical reactions occur at the atomic level even as chemical concentrations reach equilibrium (Wilensky & Resnick, 1999). Similarly, it is common for information about complex systems to be represented in dynamic quantitative and mathematical forms at the aggregate level, even while their underlying individual behaviors are not described mathematically (Blikstein & Wilensky, 2009; Stieff & Wilensky, 2003; Wilensky, 2003). Hence a primary issue in the interpretation and communication of data and mathematical models of complex systems is to infer and reason about what behaviors they may encapsulate (Author, 2010).

One way to encourage students to interpret mathematical behavior is by actually enabling them to simulate and model the phenomena that underlie it. Two decades of work has explored how this can be done with dynamic phenomena such as motion (Kaput, 1994; Nemirovsky, Tierney, & Wright, 1998; Stroup, 2002), banking (Wilhelm & Confrey, 2003), and other physical scenarios (Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Yerushalmy, 1997). This is not limited to systems where patterns are generated by and reflect a single causal mechanism, but also collections of mechanisms – Confrey and Smith have shown that multiplicative reasoning can be supported by considering individual elements in a collection each "splitting" to create exponentially more entities (1995). Doerr has shown that even the relationship between probabilistic collective behavior and theoretical idealized models can be explored by students by juxtaposing theoretical and empirical models (2000).

We are exploring the potential for *agent-based modeling* (ABM) environments to provide a flexible context for students to learn about quantitative / mathematical patterns that represent complex dynamic systems. In an agent-based model, individuals that comprise a given complex system are simulated by computational *agents* whose behavior and interactions are governed by simple rules. Each agent executes these rules iteratively to simulate a collective emergent outcome, which can be expressed both visually and quantitatively with numbers and plots. While ABM has been shown to help students make sense of the relationship between individual and aggregate behaviors in many *scientific* domains (Jacobson & Wilensky, 2006), we argue that it can also be used to support students as they explore trends represented via data and mathematical models (Authors, 2009).

Of course, any multirepresentational environment is successful only insofar as its representations relate to educationally relevant tasks and students' existing knowledge (Goldman, 2003; Kaput, 1998). To the extent that complex systems are described at multiple levels using multiple representational systems, we argue that it is very much an educationally relevant task to students to navigate and coordinate those descriptions and representations. In this paper, we concern ourselves with supporting students in accomplishing this task by exploring how well the representations that students interact with while engaging in agent-based modeling resonate with and build upon their existing knowledge.

Research Question

We are interested in how students' interactions with agent-based modeling and associated representations can help them make sense of the relationship between a collective, quantitative pattern exhibited by a complex system, and the individuals, behaviors, and interactions that pattern encapsulates. Toward this end, we utilize design-based research to answer the question: <u>What representational supports made available through our agent-based modeling activities led students to *attend to* the particularities of the encapsulated individual-to-collective relationship in complex systems, and what supports do they use to *resolve* the relationship that leads to those particularities in population dynamic systems?</u>

Methods and Design

Participants

We draw our data from two iterations of a 200-minute classroom-based educational intervention implemented across six classrooms at two public metropolitan high schools in the Midwestern United States. "Preparatory High" (PH) is an academically selective senior high school with a student population of over 1,000. At the time of our study, roughly one-third of PH students were identified as low-income, about 40%, 30%, 25%, and 5% as White, Asian, Hispanic, and Black/Native American/Other, respectively, and over 98% of students met or exceeded state standards. We conducted our intervention in two AP Biology classes, each which included between 20 and 25 students from grades 10 through 12 who were simultaneously enrolled in Precalculus, Calculus, and/or Statistics courses. "Local High" (LH) is an open enrollment senior high school with student population of less than 200. At the time of our study, 99% of LH students were identified as low-income, 100% as Hispanic, and about 25% met or exceeded state standards. We conducted our intervention in four Precalculus classes at LH, each having between 15 and 25 students from grades 10 through 12. Both schools had high numbers of students that met or exceeded expected levels of growth as predicted through state standardized exams.

Design and Activities

Our implementation included the use of a *modeling toolkit* and *associated activities*, each which reflect our design hypothesis regarding what aspects of the environment may attune students to the complex connection between individual and collective behavior. Though it is beyond the scope of this paper to review our design in detail, it was heavily informed by projects including SimCalc Mathworlds (Roschelle & Kaput, 1996), Algebra Sketchbook , Modeling4All (Kahn, 2007), Agentsheets (Repenning & Ambach, 1997), Trips (Clements, Nemirovsky, & Sarama, 1995), Function Probe (Confrey & Maloney, 1996), My Graph Rules (Wilensky & Abrahamson, 2006), and various population dynamics activities (Blanton, Hollar, & Coulombe, 1996). The three supports emphasized by these tools and activities that we examine in this paper include the *graphical noise* produced by agent-based models, the *behavioral descriptions* used to create the models, and *spatiotemporal visualization* of agent behavior in models synchronized with plots of the quantitative patterns that emerge from their execution.

The Modeling Toolkit

The modeling toolkit utilized by students in our study consisted of new construction and analysis modules for the NetLogo agent-based modeling environment (Wilensky, 1999). The first module, DeltaTick (Figure 1), enables users to rapidly construct computational agent-based models from a library of visual programming blocks that each represent behaviors, constraints, or quantities that may be of interest when modeling quantitative trends within a specific domain of inquiry. For the population dynamics activities described in this paper, we used a library that provided students with agent instructions such as "reproduce" and "die" with certain probabilities, "wander" around a spatial world, and constrain their reproductive and death behavior based on environmental or individual "if" statements (concerning the availability of space or partners or an agent's age) factors. The full set of "behavior blocks" available for students to construct models from is featured below. The second module, HotLink Replay (Figure 2), enables users to replay a simulation, and interact with enhanced plots that enable the user to click on a given graphical feature and observe that point of time in the visualization of the simulation, to overlay and compare graphs across simulations, and to zoom in and annotate specific regions.

The Classroom Activities

Over the course of each 200-minute implementation, students completed a set of activities designed to help them recognize and build connections across individual and quantitative aggregate behavior in population dynamic models. For the purposes of this paper we focus our analysis on two activities that were completed at both sites: the "Probabilistic to Exponential" activity and the "Make Graph Fit" activity. In "Probabilistic to Exponential", activity students were guided through the construction of a simple simulation wherein 100 computational agents each have a .01 chance of reproducing

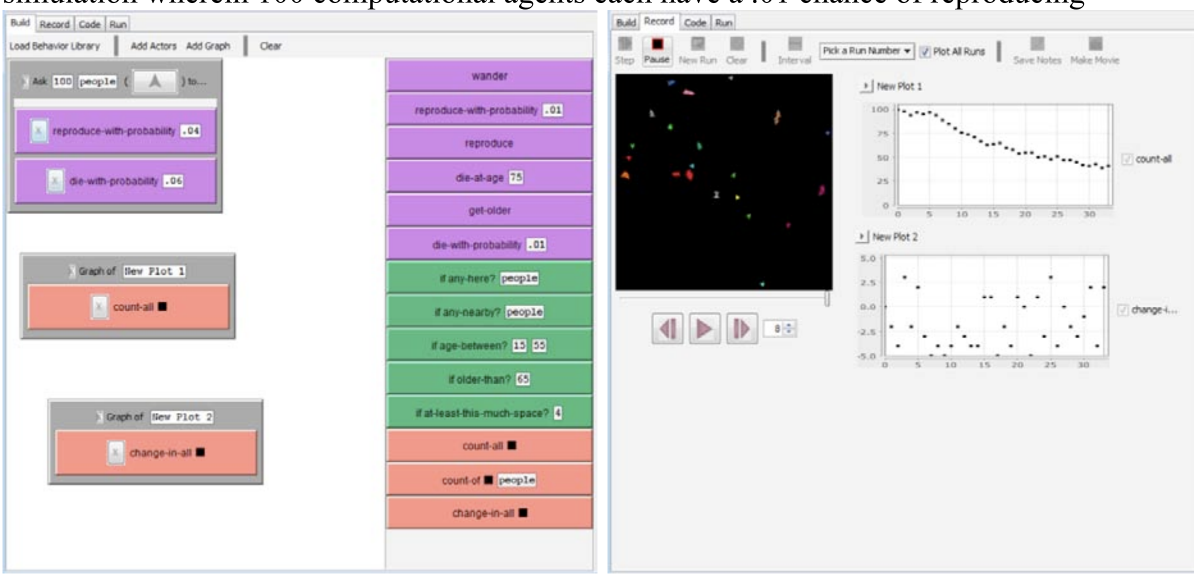

Figure 1. The *DeltaTick* (left) and *HotLink Replay* (right) modules.

per unit of time, and plots of both the number of births and the total number of people per iteration of time were tracked. They were then asked questions designed to emphasize the connection between the "noisy" data and the standard exponential population growth model. In the "Make Graph Fit" activity, students were provided a collection of population patterns including exponential decay, relative stability, logistic-like growth, linear-like growth, and density-induced growth (whereby individuals reproduce only when spatially near others), and asked to find combinations of behaviors that recreated each pattern.

Data Collection

During each implementation, groups of 2 to 3 students worked on laptops equipped with Camtasia Screen Recorder Software, which enabled us to capture and synchronize students' on-screen activity with their group discussions as captured by video cameras mounted within each laptop computer. These captured videos were then segmented by activity sequence and transcribed using Inqscribe Transcription Software. Since for the purpose of this paper we are interested in students' interaction with the designed tool and the role that activity prompts played in guiding students to attend to the connections between individual behavioral and aggregate quantitative representations of population dynamics, we focus our current analysis on the collection of video data segments that capture the Probabilistic to Exponential and Make Graph Fit activities.

Analytic Approach

To explore our primary research question, we coded each activity segment video to for the students in a given group *questioned* a representational support or *attended to* the fact that a support illustrated a particularity between individual and collective system behavior, and *resolved* to actually explore and better understand that relationship. By "explore and better understand the relationship", we mean attempting to resolve the particularity. We attended both to supports that we hypothesized would emphasize individual-to-collective connections (graphical noise, behavioral enactment, and temporal visualization) as well as unexpected supports that emerged from our data in order to pursue the dual goals of testing our existing hypothesis regarding how agent-based modeling can engage and support students in reasoning about the "individual-to-collective" relationship, while also identifying other potential supports that represent additional pathways for learning (Cobb et al., 2003).

Results

Since we are interested in exploring our hypothesized supports as well as identifying those that emerged from students' interactions with our designed environment, we present our results in two sections. First, we describe students' interactions with our three hypothesized supports for bridging quantitative to individual differences: graphical noise, behavioral enactment, and spatiotemporal visualization. Second, we briefly review other supports that students leveraged to question and begin to interpret the relationship between individual probabilistic and collective quantitative behavior.

Designed Supports for Bridging Quantitative to Individual Descriptions Graphical Noise

We expected graphical noise to alert students to the complex relationship between individual behavior and collective quantitative trends by emphasizing the probabilistic nature of the underlying behavior that graphs measured. Specifically, during the "Probabilistic to Exponential" activity, we guided students to construct a graph measuring the *change in population* to emphasize that the probabilistic nature of individual agents' reproduction manifested quantitatively. We found that while nearly half (7 out of 16) of the groups explicitly questioned the noise produced by the *change in population* graph even before they were prompted to do so by the accompanying activities, only one group found this to be enough motivation to explore the issue in more depth. When explicitly prompted to explain the noise in the accompanying activities, many groups did in terms of the relationship between change and accumulation in the available graphs, without connecting to probabilistic agent behavior.

Initial Questioning 7/16 groups	**Change Explanation 1/16 groups no prompting 7/16 groups prompting**	**Probabilistic Explanation 3/16 groups prompting**
"Like, it's going up and down..." "Wow, why is it doing that? … Is this derivative? I don't think so… Why is it crazy?" "Like, it's...the graph is kind of like random"	Ana: I don't get the random dots. Jorge: They're not random. It's just...it's showing you the...let it get to 150 and I'll.. Alright let's go right here (zooms in to plot of change). 175 (zooms in to plot of population). It's just the change in one relation. So like from here...(adjusts graphs). Do you get what I'm saying, though?	"It says sometimes the graph of change-in-all goes down, even though the population is always growing. Because there's still probability that they might not have any...that they might not reproduce at all."
Other groups described the noise as the result of death, (1), an inherent feature of the program itself (1), or could not be classified (3).		

Individual Behavioral Enactment/Programming

A second factor that we expected to alert and support students in attending to to the connection between individual behavior and collective quantitative patterns was that during both activities, students engaged in the programming of individual rules as behavioral descriptions. We expected that when reasoning about the quantitative patterns generated by those models, students would recall either generic descriptions of individual behaviors that contribute to population growth (for example, notions of "having babies", "dying", or "counting people") or reference to the specific individual instructions they programmed ("one guy reproduces by 1%", "die with probability .05". Unlike the noise revealed in graphs, students did not express that the behaviors they programmed into the simulation and the resulting outcomes were inconsistent or unexpected. However, when they were asked to explain what individual behaviors contributed to the resultant trend in the "Probabilistic to Exponential" activity, they often did in only a generic form "change in population", "reproduction". It was not until the "Make Graph Fit" activities that students described trends in terms of the specific rules they programmed "reproduce by 1%", "die with probability .05". While it is not surprising that students would refer to the rules they used when working to build models in order to interpret their resultant behavior, this does illustrate the potential for construction activities to emphasize the multivariate, "encapsulative" nature of patterns in complex systems.

	Generic Explanations **8/16 groups Prob to Exp** **5/13 groups Make Graph Fit**	**Rule-Based Explanations** **3/16 groups Prob to Exp** **8/13 groups Make Graph Fit**
Probabilistic to Exponential	"I was thinking that maybe this relates to this, because it's actually telling you how many times they actually reproduce, which helps you understand what's going on..."	"Because individually they're still subject to reproduce by 1%. Over the long run, though, it increases..."
Other groups provided change-based descriptions (2) or could not be classified (3).		
Make Graph Fit	Herman: Give them their space. You can't reproduce that much. Eric: Alright...it's falling down. Janet: It's not growing fast enough.	John: It's not going to like replace though. Because if one guy reproduces, he'll make one new person. Whereas, if, if it's .99, then 99 people die. Franco: No. John : They wouldn't replace each other, though. Franco: Chance too high. John: They just die.

Spatiotemporal Visualization

Finally, we expected the side-by-side and synchronous nature of a spatiotemporal, agent-based visualization and a quantitative plot to emphasize that those quantitative patterns emerged from counting the addition and aggregation of individual agents. We found that few groups attended to this relationship during the "Probabilistic to Exponential" activity (only 2/16 groups mentioned any features of the visualization, and one group only did so to note that they hadn't paid attention to the visualization). In the "Make Graph Fit" activity, as students built models that featured spatial and interactive behaviors, they relied more on visualization to understand how those features led to patterns such as logistic growth (5/13 groups observed whether their behaviors played out in visualizations).

Emergent Supports for Bridging Quantitative to Individual Descriptions

Questioning Measurement of Behavior. The first, and perhaps the most impressive, support that led students to critically examine the relationship between simulated individual behaviors and the quantitative patterns those behaviors produced was to question what, exactly, each quantity was measuring. In our design, we expected that asking students what agent behaviors would *change* population would lead students to view population as encapsulating those behaviors. Instead, the results above imply that they may have seen the two factors as *related* without exploring whether they were explicitly causal.

Modeling Assumptions

A second support that led students to examine the relationship between individual and quantitative behavior was to question the assumptions about human behavior that underlied a given set of programmed rules. This manifested itself dramatically when one group of students questioned whether agents exhibited a 9 month gestation period or reflected any assumptions about a given demographic populations' behavior. The group then decided that in order to better understand the underlying assumptions of the model, they would conduct experiments with a single individual under different rules. This led them to consider how that single individual would influence a population.

The Reversibility Script

Finally, several of the students from our first research site, PH, used clues from the questions we asked in our activity set (including questions regarding the relationship between change and population graphs, and regarding the meaning of "change") to infer that it was a calculus-based reversibility relationship, rather than an individual-to-collective relationship, that was the main goal of their exploration. While these two concepts are not mutually exclusive, this "graphical/quantitative reversibility" appeared to supplant students' potential exploration of individual-to-collective behavior using the environment.

Discussion

We sought to identify what designed and emergent supports can help students to understand and navigate the relationship between quantitative patterns generated by complex systems, and the individual behaviors that underlie those patterns. We found that three supports – graphical noise, behavioral enactment, and spatiotemporal visualization, each played differential roles in drawing students' attention to and supporting their investigation of this relationship. We also identified emergent supports – specifically, the potential for framing graphical noise in the context of questioning what, exactly, is being measured; engaging students in discussions about the assumptions that underlie a given agent-based or mathematical model; and *downplaying* the reversibility of graphs until connections to the underlying behavior of a model is established, as potential paths forward in our development of computational modeling tools to support students as they engage in the new forms of mathematical thinking that are required in an age of complex systems.

REIFICATION AND ABSTRACTION: DEVELOPING MATHEMATICAL CONTENT KNOWLEDGE THROUGH DISCOURSE AROUND ALGEBRAIC REASONING AND PROOF

Henry Gillow-Wiles
Oregon State University
gillowwh@onid.oregonstate.edu

Margaret L. Niess
Oregon State University
niessm@onid.oregonstate.edu

Moving from a reliance on physical representations of mathematical concepts or ideas like addition to a more abstract, mathematical object based understanding is a critical event in developing mathematical content knowledge. In a mixed methods study involving twelve in-service elementary and middle school teachers taking part in a two-week summer institute as part of an online Masters in Science program, the impact of using discourse-based teaching and learning strategies on developing their algebraic reasoning and proof understanding of their mathematical content knowledge was investigated. Using a combination of qualitative and quantitative data sources, a case-study analysis revealed that the teachers who increased their content knowledge made significant shifts in their investigations of mathematics concepts. These changes were evidenced by a movement from using discourse that relied on physical representations and examples to basing their discourse on properties, axioms, and generalized characteristics.

Introduction

Through leadership from NCTM and supported by the Common Core Standards, increased emphasis has been placed on the fostering and supporting of mathematical reasoning and justification as key educational elements in addressing mathematics educational reform needs (NCTM, 2000). Educators responding to these 21st century reforms for mathematics have identified continuing professional education supporting teachers in developing their own mathematical content and conceptual knowledge and understanding as critical for meeting this challenge (NCTM, 2000). The need for extending teachers' mathematics knowledge is in response to an increase in the level of mathematics proficiency required of primary and elementary teachers in order to prepare their students for success in making the all important transition from arithmetic, based on physically represented procedures, to the abstracted concepts of mathematics (Gray & Tall, 1994). This transition process begins with the introduction of algebraic topics and quite often continues for the remainder of a student's academic career (Sfard & Linchevski, 1994).

Research Question

As part of an online three-year Masters of Science program, a two-week long summer institute focusing on the development of algebraic reasoning and proof skills was conducted. In the context of that summer institute, the research question for this study is: what is the impact of using discourse-based instructional strategies focused on developing teacher's algebraic reasoning and proof understanding on their mathematics content knowledge?

Perspectives and Theoretical Framework

All too often, teacher preparation and licensure programs place more emphasis on methodology, pedagogy and practice than on content knowledge. This shift in emphasis often results in a focus on physically represented procedure with reduced attention to underlying abstract concepts. Additionally, the important role played by the dynamic relationship between procedure and concept in understanding and solving problems from world experience is seldom accessed or investigated.

In response to the importance of understanding how procedural and conceptual mathematical knowledge frame and inform the other, Gray and Tall (1994) presented their model of the role embodied objects play in learning mathematics. Their work, taking from Skemps' (1976) work on relational and instrumental understanding, described learning mathematics as "occurring in a biological brain" (E. Gray, Pinto, Pitta, & Tall, 1999, pg. 1) and could be investigated with support from a cognitive psychological perspective (Tall, 1999; Watson & Tall, 2002).

Continuing with research in mathematics learning using a cognitive psychology perspective, Sfard (1991) described abstract concepts as having two fundamentally different conceptualizations: "structural" and "operational" (Sfard, 1991, pg. 3). In Sfards' perspective, these conceptions of mathematics concepts, are instrumental in the process of learning and problem-solving. It is the interplay between a structural or object view and an operational or process view that frame and support the development of meaningful mathematics knowledge and understanding (Sfard, 1991; Sfard & Linchevski, 1994).

As these theories of mathematics learning developed, understanding the process of transitioning from a concrete, computational operations understanding to abstract objects understanding became a focus of research. Sfard & Linchevski, (1994) described this as a three part process, ending in "reification" (Sfard & Linchevski, 1994, pg. 20), or the ability to see something familiar in a new light. Moving through the transition process indicates a development of mathematical thinking that is difficult for learners to accomplish as well as for teachers to facilitate (Gray & Tall, 2001). In similar research, Edwards (2005) looked the transition from elementary to advanced mathematical thinking, defined as "thinking that requires deductive and rigorous reasoning about mathematical notions that are not entirely accessible to us through our five senses" (Edwards, Dubinsky, & McDonald, 2005, pg. 17). One characterization of advanced mathematical thinking is the development of the knowledge and reasoning skills to meaningfully think about problems where the concept of infinity plays a central role.

The importance of being able to move between these two perspectives of mathematics, (i.e. a concrete representation view versus a definition and axiomatic view), provided motivation for research into how this knowledge is developed. Gray and Tall (2007), extending their work in 1994, describe the role of language in providing pathways for the "compression" (Gray & Tall, 2007, pg. 2), where the brain is able to filter out irrelevant information and compact the important concepts, through a process where language plays a critical role. While important information is first just noticed in the thinking process, it is only when language is used to name the concept that the compaction process can result in the development of what Gray and Tall describe as a "thinkable object" (Gray & Tall, 2007, pg. 3).

The use of language as discourse in learning mathematics is the focus of the work of several researchers. Sfard (2003), taking a social constructivist approach and building on work by Vygotsky (1929) and Lave and Wenger (1991), describe a model of language, not just facilitating learning, but language *as* learning. In this model thinking is characterized as communication, whether internalized dialogue or externalized exchanges. It is this internalized dialogue, where concepts and ideas are named and objectified, that facilitates development of abstract, conceptualized understanding (Sfard, 2003). The use of language and discourse in helping students make the transition from a computational view of mathematics to a view based on abstract mathematical objects is centered on the need for using language to name abstract objects in order to think about them (Davis & Tall, 2002; Sfard, 2003; Tall, 2007; 2008; Umland & Hersh, 2006). It is precisely this perspective of the use of language that framed and supported the collection and analysis of the multiple data sources in investigating how the use of language in discussion and shifting usage patterns impact the development of the interplay between concrete, computational and abstract, objectified mathematical understanding.

Context and Methodology

This study was conducted in the context of the first year of a three year online Masters of Science degree program that focused on the integration of technology with science and mathematics instruction. Twelve K-8 teachers were selected from several school districts over a diverse geographical region covering approximately 500 square miles. The twelve teachers were part of a three year MSP grant project that included a face-to-face two-week summer institute consisting of a 3-credit mathematics content course and a 3-credit science content course.

The mathematics content course focused on the development of algebraic reasoning and proof skills and understanding. Each day, the students were presented with problems, ideas and topics for discussion. These problems used as problem solving prompts were sequenced to lead the students from concepts that could be explored through concrete examples, such as calculating the number of sodas consumed on the *n*th day if there had been 6 sodas consumed on the first day and 3 more each day after, to concepts and ideas where examples served as a starting place for more meaningful investigation and inquiry, for example determining the sum of the first *n* odd positive integers.

The mixed-methods structure used was a sequential explanatory design framework (Ivankova, 2010) where the quantitative data revealed changes in student understanding in both algebraic reasoning and proof knowledge. The qualitative data was collected in an effort to develop an understanding of the underlying elements of the classroom experience that influenced these changes.

The data collection and analysis methodology were structured to support a case-study analysis. This mode of inquiry was chosen to provide insight into both the changes in mathematical content knowledge as related to changes in algebraic reasoning and proof as well as if and how the students made the transition from a computational to an abstract perspective of mathematics.

The design of the case-study analysis methodology was framed by the work of Onwuegbuzie, Johnson and Collins (2009), where they presented philosophy of research that supported the use of mixed-methods designs and provide a typology of analysis strategies. This typology indicated that a case-study analysis was most appropriate where the goal is to "analyze and interpret the meanings, experiences, attitudes, opinions, or the like of one or more persons" (Onwuegbuzie, Johnson, & Collins, 2009, pg. 117).

Data Collected

Each day, as a result of their activities, the students produced written artifacts which were collected. These most often consisted of written scratch work, drawings, charts and illustrations used in problem solving and knowledge construction. In addition to these written artifacts, a video record of the verbal interactions during the classroom activities was made. This video captured both small group and whole group conversations where the students were engaged in sense-making interactions as well as expositions of ideas to the entire group.

In addition to this qualitative data, two different quantitative measures were utilized. The Diagnostic Teacher Assessment of Mathematics and Science (DTAMS) middle school algebra strand assessment was used in a pre/post-test context (Saderholm, Ronau, Todd Brown, & G. Collins, 2010). This assessment has a subscale focusing on mathematics content knowledge and a subscale that focuses on algebraic reasoning, allowing for gathering information about changes in both content knowledge and algebraic reasoning skills. This assessment was given on the first (pre-test) and last days (post-test) of the summer session. To assess changes in the students' understanding of proof, a diagnostic focusing on students' skills in constructing proofs from familiar and novel problems was used in a pre/post test context, also given on the first and last days of the summer session (Healy & Hoyles, 2000).

Data Analysis

Analysis of the quantitative data was accomplished through the use of an independent samples t-test with the teachers as the unit of analysis. The qualitative data was analyzed through an open coding process where the written and video data was coded following procedures developed by Corbin and Strauss (1990). The frame work for coding the qualitative data was based on Harel and Sowder's concepts of proof frames, where they describe a progressively increasing level of knowledge and sophistication in use of proof and algebraic reasoning to construct and communicate mathematics knowledge based on moving from a dependence on an inductive perspective based on random examples to using a deductive proof structure based on definitions, axioms, and logic (Harel & Sowder, 1998). This description process, using coding categories developed from characteristics of the different levels of proof abilities and knowledge framed by Knuth and Elliott (1998), identified changes in participant levels of proof understanding.

A case-study analysis was used to identify and describe any progress each student made in shifting from a computational perspective of mathematics to one based on abstract concepts. This identification process was framed by the work of Sfard and Linchevski (1994) in their description of the reification process[1] and by the work of Tall (2008) in his description of the transition process from a reliance on concrete examples to more formal, axiomatic mathematical thinking.

Results and Conclusions

Differences in Algebraic Reasoning and Proof Skills in Pre/Post Assessments

Assessment	Means: Pre-intervention	Means: Post-Intervention	t-value	p-value	Effect Size
DTAMS					
Content Knowledge[1]	.56	.76	-2.94	.032	.44
Reasoning and Problem Solving[2]	.51	.94	-3.02	.006	.54
Proof Construction Assessment[3]	2.08	3.58	-3.00	.012	.49

1. Mean score on a scale of 0-1. 2. Mean score on a scale of 0-2. 3. Mean score on a scale of 0-4.

Results of an independent samples t-test, comparing pre and post intervention mean scores, reveal a significant increase in the students' mathematical content knowledge, algebraic reasoning skills and their ability to construct algebraic proofs from familiar and novel contexts ($p<.05$ in all cases) with a large of substantial effect size (>.4 in all cases).

Through the coding process, it became apparent that there was a definitive shift in the content of both the written and the verbal sense-making interactions, where the participants' vocabulary and written word choices shifted from describing mathematics concepts in terms of concrete examples to describing mathematics concepts in terms of definitions and properties. The goals identified by the students for the problem-solving activities also evolved from finding a "solution" to developing their understanding of how the mathematics concepts or ideas in question could be extended to more generalized ideas, creating new (to them) connections and relationships.

The results of an analysis of the qualitative artifacts of the mathematical discourse engaged in by the students described how they developed their mathematical knowledge through mathematical discourse centered on making a transition from thinking based on computations based on examples to thinking based on definitions, properties and relationships.

The primary evidence for this transition came in the form of clearly presented changes in how the students talked about mathematics, both in their problem solving activities and when they were explaining their ideas. Analysis of video data revealed a shift in how the students talked about mathematics, both in their use of mathematics vocabulary and their use of mathematics notation in the context of displaying their ideas during sense making activities.

Day two:

Student A, in a discussion with another student: "I'm not sure how many examples we need to try. I checked a few numbers and it worked for all of them, so I'm OK with it".

Day seven:

Student B, in a small group discussion about the idea that adding two even numbers results in an even number: "I tried a bunch of examples and I think it has something to do with what makes an even number even. How do we need to define an even number to make sense of this?"

Student C, in same group discussion, "We need to write an expression that represents adding two even numbers where we use variables to represent the even numbers, not just examples of even numbers."

Their initial written work portrayed the use of primarily guess and check methodologies based a limited number of concrete examples, while artifacts from the end of the course presented multiple problem solving strategies used in concert to reveal patterns and relationships based on generalized properties and definitions.

These shifts from primarily computational methods based on concrete examples to more axiomatic, properties-based methods illustrated how the students' thinking shifted from a concrete, computational understanding of mathematics to an abstract, conceptual understanding. Initially, the students attacked each problem with a guess and check methodology, using examples in their sense making activities. At times, there were no reasons given for the choices of examples.

Day one:

Student D, displaying her work to the whole group and responding to a question about why she chose her examples, "I just used easy numbers, like 1, 2, and 3."

As the students spent time engaging in problem solving activities and developing their understanding of proof, they began to be unsatisfied with the limitations of understanding based on examples. Questions about generalization of ideas, properties and concepts became the focus of discourse, where extended discussions helped frame and develop shared knowledge.

Day 8:

Student A, in a discussion with another student about summing the first n positive odd integers and how to show that the summation equals n^2*, "I think we need to talk about odd numbers like we did with the problem about adding even numbers, with an expression instead of examples. That way we can add up the expressions and see how that might simplify to* n^2*."*

As the students became more adept at asking the kinds of questions that better represented their thinking processes, they became better at using questions to help craft their understanding and knowledge. The development of their questioning strategies implied a development in their thinking. Moreover, since the problems they were using as prompts for their investigations centered on aspects that were not accessible to them through examples, (i.e. infinite sums), their thinking necessarily shifted to a more advanced mathematical thinking structure (Edwards et al., 2005). This change in thinking, represented as changes in speaking and writing patterns (Hilbert, 2008), indicates a transition from an operational, through a structural, to a functional perception of algebra as described by Sfard & Linchevski (1994) or from a procedural, through a process to a procept (melding of process and concept) perception of mathematical thinking detailed by Gray, Pinto, Pitta, and Tall (1999).

Implications

Helping teachers extend their mathematical content knowledge is critical. Continuing education opportunities that support the development of conceptual mathematics understanding and the ability to smoothly shift between computational and abstract conceptual perceptions provide the teachers with a foundation of knowledge on which they can build, thus facilitating their mathematics teaching and the learning of their students. Structuring educational experiences where teachers have opportunities to engage in sense making of abstract mathematics concepts used in concert with computational mathematics to develop sophisticated problem solving understanding and strategies provides a framework where teachers are able to develop their own knowledge and skills of mathematical thinking. With well developed understanding, teachers are better equipped to help their students be successful on the same mathematical journey.

Continuing research towards a more complete understanding of how to help students (and teachers) better make the transition from a procedural understanding of mathematics to a more conceptual understanding and how to effectively use these different perspectives in problem solving and sense making activities would further efforts to make this difficult transition easier and more successful.

Endnotes

1. In this context, the term "reification" refers to converting processes applied to accepted abstract mathematical objects into self-contained static constructs in their own right (Sfard, 1991)

[1]A TEACHING EXPERIMENT TO FACILITATE CONCEPT MODIFICATION: ASYMPTOTES, LIMITS, AND CONTINUITY

Girija Nair-Hart
University of Cincinnati, Clermont
girija.nair-hart@uc.edu

After identifying students' concept images of rational functions , asymptotes, limits and continuity using a two-hour long problem solving interview, a four-week, eight sessions teaching experiment was conducted. While the teaching experiment helped the researcher understand how students developed their conceptual models of the concepts of asymptotes, limits, and continuity of rational functions, it also helped the researcher to investigate effective instructional practices that help facilitate mathematics learning with conceptual understanding. This paper summarizes the importance of student centered analysis, deconstruction, modification, and reconstruction of preexisting concept images in order to foster conceptual understanding of a newly introduced concept.

Purpose of Study

The purposes of this research were guiding students towards (1) summonsing a deeper understanding of the concept of asymptotes (2) helping them see the connections between the concepts of asymptotes and limits, and (3) affording them to use that connection to enhance their understanding of the concept of limits.

Asymptote, a concept that is closely related to the concepts of limits, continuity, and indeterminate forms is usually introduced to students in the precalculus course. Students often struggle with these concepts even in university analysis courses (Juter, 2004). Through a two-hour long problem-solving interview, the researcher investigated university calculus 2 students' conceptions of asymptotes and the connections between asymptotes, limits, and continuity. Nineteen students were interviewed using the problem solving instrument CORI that constituted problems requiring thinking *out of the box*.

The problem solving interview revealed that students generally possessed a process-oriented view towards mathematics problem solving. While holding numerous incomplete conceptions regarding rational functions, their asymptotes, limits and continuity, students also failed to establish connections between these closely related concepts. Students were unable to explain the behavior of functions around its asymptotes and they were unable to relate the asymptotic properties of functions in terms of limits. Without being able to relate to the ways in which function behavior was affected by its asymptotes, students were unable to find limit at infinity and infinite limit without a graphing calculator.

In light of the conceptual obstacles noted, a series of teaching episodes were carried out to help students attain essential modification in their conceptions of asymptotes, limits, and continuity. During the teaching episodes, a variety of activities that would encourage critical thinking and exploration of conflicting ideas were implemented.

Theoretical Framework

The prime goal of this research was to gain a deeper understanding of the complex cognitive processes involved in learning mathematics and the implications of those cognitive processes for mathematics instruction. Therefore, the theories that framed this research explored several crucial aspects of concept, and concept formation (Piaget, 1970; Tall & Vinner, 1981) in addition to knowledge and knowledge acquisition (Skemp, 1971). Theories of concept representation (Goldin & kaput, 1996) also influenced this research study.

Piaget asserted that students do not come to our classes as *blank slates*. The variety of notions students hold regarding a particular concept could be influenced by former formal or informal exposition to the concept. At times, prior experiences with a certain concept could negatively interfere with the newly introduced aspects of the concept. Piaget referred to these internal conceptual conglomerations as schema, while Tall and Vinner (1981) referred to these conceptual entities as concept images. Many associated images are consciously or unconsciously summoned while recalling and manipulating a concept. Concept images could seriously influence students' interpretations of the newly introduced mathematical concepts unless they are given the opportunity to consciously challenge and modify the pre-existing internal schema of the concept in accordance with the new conceptual input (Piaget, 1970; Tall & Vinner, 1981).

Goldin and Kaput (1996) elaborated on different ways of capturing experiences through their theory of representation. They argued that representation is a complex cognitive process that is signified by personal and idiosyncratic aspects or cultural and conventional aspects (Bruner, 1966, Goldin & Kaput, 1996). According to Goldin and Kaput there are internal (mental) and external (physical) representations. Internal mental representations involve the use of mental images. These mental images could be pictures, diagrams, or even written items such as words and definitions .These imageries do not include every detail of the object or every action performed on them but recall their important characteristics. These internal mental processes, though not directly observable, are often inferred by educators and researchers through external behaviors (words), or actions (problem solving).

Since there are different types of representations for human knowledge, different people have different mental images of mathematical contexts. For example, before formally learning the *concept of limits*, students are familiar with the *terminology limit* in daily life. The meaning of this word is interpreted differently by different people. For instance, when referred to an *off limits* situation, the meaning of *limit cannot be attained* is implied while in another situation such as *age limit* 5, the implication is that the *limit cannot be surpassed*. Due to this confusion, students acquire different meanings and interpretations while dealing with the concept of limits. One such dilemma causes uncertainty in students whether limit can be obtained, or can be surpassed.

In this instance, how is concept modification possible? According to Piaget's (1970) and Skemp's (1971) theory of knowledge acquisition, knowledge or a concept is meaning-driven and is actively constructed by the learner. Accordingly, concept is formed through experience and through classification and abstraction. Gathering together experiences through similarities is termed classification while the process of identifying similarities among experiences is called abstraction. The efficacy of concept images depends up on the level of proficiency and flexibility with which the person acquired the conceptual knowledge. Since learners are active builders of knowledge, not passive receivers of information, I was curious to explore ways in which active construction of mathematical knowledge could be facilitated and how meaningful learning that is less vulnerable to misconceptions could accomplished. I posed that active and meaningful construction of mathematical knowledge could more likely be recognized by constructivist instructional model.

From a constructivist viewpoint, knowledge mediation and construction can best be achieved if students are active and interactive participants in the process of learning. According to Piaget (1970), however, social interaction helps build knowledge by simply aiding the restoration of equilibrium. Constructivism has different forms. While they all support the notion of individual construction of knowledge, there are also profound distinctions. Paul Ernest (1996) discussed various forms of constructivism: weak constructivism, social constructivism, and radical constructivism. *Weak constructivism,* as Ernest (1996) describes it, assumes that there is a realm of knowledge out there which could be received via senses. Individuals personally construct knowledge to match the body of knowledge out there. *Radical constructivism* is based on the epistemology that all knowledge is being constructed by individuals on the basis of cognitive processes in dialogue with the experienced world. This form of constructivism maintains that individual knowledge is in a state of change through reevaluation via the process of adaptation and accommodation. This form of constructivism assumes no position regarding the world of knowledge outside the experience of the knower. Finally, *social constructivism* acknowledges the existence of a world of knowledge that supports the appearance we have shared access to, but which we have no way of knowing about for sure. Individuals construct knowledge with the force of language and social interaction. Thus knowledge is a social construction, a cultural product consensually negotiated by communities. Learners construct knowledge within the cultural context that gives meaning to that knowledge.

As far as the application of constructivist model to classroom teaching goes, Glasersfeld (1996) offered several pointers to help teachers create a classroom that is more constructivist and meaningful in nature. Piaget's (1970) assertion not to consider students as mere blank slates holds a substantial role in Glasersfeld's view of constructivist's classrooms. Instead, teachers were encouraged to acknowledge students' prior conceptual knowledge and how that can serve as a foundation to construct knowledge that is more meaningful (Piaget, 1970). Accordingly, the teacher must try to find out where students stand as far as the knowledge they hold prior to instruction.

According to Glasersfeld, a teacher must then try to modify students' ways of thinking of mathematical knowledge. Students must realize that knowledge is context specific, and that knowledge that is well explored within the context of discussion is more sensible. Subsequently, instead of *giving out* correct answers, a teacher must ask students how they arrived at their answer and then help them explore the reasons why the answer may or may not work under another similar circumstance. Thus, students may become proficient in making sense of their own mathematical thought process through analyzing the problem situation and by discriminating between similar and diverse circumstances.

Research Question

How can students' pre-existing concept images regarding the concepts of rational functions, their asymptotes, limits, and continuity be modified? What effect does the teaching experiment have on students' concept modification and forming connections between the closely related concepts of asymptotes, limits, and continuity?

Methodology

I conducted a small scale Teaching Experiment (Steffe & Thompson, 2000) with a small group of participants to gain insights into, and build explanations of students' mental constructions of mathematical concepts. Seven students were recruited based on their performance on the problem solving interview and also based on their immediate availability. Through a teaching experiment a researcher will be able to gain first-hand information on students' mathematical reasoning (Steffe & Thompson, 2000). Teaching experiments are usually situated within a constructivist theory of learning in which learning is believed to be happening because of learners' active construction of knowledge.

Steffe (1980) identified three major aspects of a teaching experiment as individual interviews, teaching episodes, and modeling. Teaching experiments are concerned with conceptual structures and models of the kinds of change that are considered learning or development. Modeling is the formulation of models that would explain the results of the research. In this research, modeling would explain the researcher's perception of how students construct, interpret, and refine their notions of the mathematical concepts of asymptotes, limits, and continuity.

By following Steffe's model, once students' concept images were identified after the exploratory interview, I carefully outlined the lesson plans to be used during the teaching episodes. Each lesson contained a set of problems that students were expected to solve individually. In some cases, for example, with rational functions, a packet of notes was provided that contained definitions of some concepts with examples and non-examples. Lesson plans were designed bearing in mind that in order for students' conceptual schemes to change, they should be presented with situations in which they deem their existing schemes inadequate. In such cases, the new situation cannot be solved unless students make a major reorganization in their existing conceptual schemes.

The setting of the teaching episodes was somewhat different from that of a typical classroom. There was no urge to rush; there were no deadlines to meet, and no curriculum that must be covered during these teaching episodes. In addition, direct instruction was not used and students were encouraged to first work on their own and then discuss their ideas in groups while the teacher-researcher took the role of a challenger and a negotiator of concepts. The focus was on how students' conceptual schemes changed due to specialized mathematical interactions that took place between students, between the student and the researcher, and autonomously within each student. The researcher, however, asked probing questions, provided scaffold at times, and afforded students with additional resources as needed.

Before the discussion of any mathematical concepts, I started the teaching episodes with a brief presentation of the nature of mathematical truth. At this time, a list nicknamed as *the rules to live by* were also discussed. These rules were: (1) do not try to memorize every single rule or fact you may come across, (2) mathematics does not comprise simply of memorization, (3) mathematics is a problem-solving art, not just a collection of facts, (4) do not give up on a problem if you couldn't solve it right away, (5) re-read it thoughtfully and try to understand it more clearly, and (6) struggle with it until you solve it (Stewart et al, n.d.).The eight learning episodes, conducted over a period of four consecutive weeks were dedicated to mathematics concepts of *rational functions*, *usage of correct terminology, definition of asymptotes, vertical asymptotes, horizontal asymptotes, other asymptotes, limits, finite limits, infinite limits,* and *limits at infinity*.

Teaching episodes were based on 6 assumptions on student concept formation and conceptual change. The *first* assumption was that student's concept images were influenced by their previous exposure and experience with the concept. The *second* assumption was that students actively construct their own mathematical knowledge and active assimilation, accommodation and equilibration is imperative for the full development of these conceptions. The *third* assumption was that, equilibrium can only be maintained through the active encounter with situations that may pose disequilibria in the already existing conceptual framework. *Fourth*, I assume that social interaction and argumentation are essential features of maintaining conceptual equilibrium. *Fifth*, teachers could intervene and pose cognitive confusion by simply invoking contradicting problem situations by the usage of appropriate examples or by redirecting students' attention to formal definitions and probing a constant check between intuitions and formal definitions. The *sixth* assumption is that in a situation where the second, third, fourth and fifth assumptions are realized, a teacher-researcher might be able to foster concept refinement in learners.

I believe that concept refinement becomes complete only through the processes of constant re-assimilation, accommodation, and the maintaining of equilibrium invoked by different types of cognitive demands. It should also be noted that students' mathematical schemes change only slowly, and there will be extended periods when students operate at the same learning level. For example, during the learning episodes, there were instances where some students simply *could not* differentiate between the phenomenon of a hole and a vertical asymptote. Sometimes, students who seemed to have understood a concept suddenly could lose their steadiness when the concept was presented in a newer problem context.

In the teaching experiment, the sources of data were the students and the teacher-researcher. Students and the teacher-researcher provided data in the form of audio and video tapes of the teaching episodes that were transcribed. The researcher provided field notes for all teaching episodes. Video images helped the researcher to go back and review the teaching episodes for clarification and reconfirmation of documented findings during the research. Video segments were also selected to record possible interactions suggesting that students were engaged in personal constructions of strategies to solve a problem or finding explanations for their mathematical realities.

Results

As elaborated by Tripp & Doerr (1999), the investigation focused on how shifts in student thinking occurred and in what ways such shifts in thinking supported the development of viable models. What kinds of events in their interactions with each other, with the problem situation, and with associated representations led to shifts in their thinking? This was accomplished through closely observing changes in students' interpretations and representations during the teaching episodes as they faced challenging and inconsistent problem situations that conflicted with their existing concept images.

As revealed by the initial problem-solving interview, students' incomplete concept images of rational functions fell mainly into three categories: *the rational number image, the fraction image,* and *the discontinuity image.* Students who possessed the rational number image described that the graphs of rational functions are "nice," "symmetric" "one-piece," "continuous," and "without any complications." Some students specified that like rational numbers, such as $\sqrt{4}$ and $\sqrt{9}$, these functions were "whole." These students' concept image of rational numbers were restricted to that of numbers like $\sqrt{4}$ and $\sqrt{9}$. The rational number conception was the most prevalent conception that students held of rational functions.

Some students believed that rational functions assumed fraction forms with no variable in the denominator and accordingly no asymptotes or discontinuity existed in their graphs. However, those students who held the discontinuity image believed that all rational functions had variables in the denominator, and therefore their graphs were discontinuous, they came in several pieces, and had vertical asymptotes. During teaching episodes the concept of rational numbers were first explored. This was done by definition analysis: examining the definition of rational number, analyzing the meaning of the term *rational,* and examining polynomial functions. During this session students were curios to explore the basic structure of rational numbers and realize that rational numbers include a wider variety of other numbers in addition to numbers like $\sqrt{4}$.

Limited perspective on rational number concept, the connection between rational and fraction form as perceived by students *with no variable in the denominator* had clearly affected student conception of rational functions and their properties. These various prior notions needed to be re-configured in order to assign new meaning to the concept of rational functions.

Student notions about asymptotes in general fell in to the categories of the *three-piece graph image*, the *invisible line image,* and *the no-concurrency image*. The three-piece graph image reflects graphs with two vertical asymptotes and one horizontal asymptote that were symmetric with respect to the Y-axis. Three-piece graphs were also comprised of graphs with two vertical asymptotes (VA) and no horizontal asymptote (HA) and were symmetric about the origin. Students also believed that asymptotes were dotted lines the graph approached but never reached. The no-concurrency images held by students lead them to believe that a graph must never be concurrent with any of its asymptotes.

During teaching episodes, analysis of the definitions of the function concept, the independent and dependent variables, were instigated before the definition of asymptotes were discussed. These deliberations helped settle a big issue of terminology concerning *what is approaching what*; for example is it *as x approaches a, y approaches b or is it as y approaches b, x approaches a*? The various meanings of the word *approach* as students perceived them were also discussed in addition to each student elaborating on and debating over what their notions of asymptotes are and the reasons behind each of those notions.

Various textbook definitions of the concept of asymptotes were analyzed. During this time students unanimously pointed to the popular textbook definition "informally speaking, an asymptote of a function is a line that the graph of the function gets closer and closer to as one travels along that line." After examining this definition in regards to both vertical and horizontal asymptotes the dilemma was resolved and the unanimous decision was reached to amend the informal definition by specifying that *the curve was allowed to cut through the HA as long as it came back and approached the horizontal line or that the end behavior of the function should be such that it must approach the asymptote.* It was also noted that if a curve was to cut through the vertical asymptote, it could not come back and approach the vertical line, since this behavior would violate the function requirement. Students further elaborated that asymptotes of the graph of *non-functions* could very well intersect vertical asymptotes as well.

Regarding particularly on vertical asymptotes, students held a variety of notions. All students associated vertical asymptotes in connection with multiple views of undefinedness. Most students stated that *vertical always occurred at points where the function was undefined.* Though a few students who knew about the possibility of having either a hole or a vertical asymptote at the points were the rational function was undefined, they were unable to distinguish between the conditions under which a hole occurred for a rational function. Even though students had seen graphs with holes and have realized that the function would be undefined there, many of them were unable to differentiate between the function behavior around holes and around vertical asymptotes. The confusion between holes and vertical asymptotes seems to have stemmed from noticing no distinction between the $\frac{0}{0}$ and $\frac{b}{0}, b \neq 0$ forms.

I encouraged students to examine their own newly reconstructed definition of asymptotes to establish the condition/s that warranted the occurrence of vertical asymptotes. To challenge beliefs such as "a curve could not intersect its VA", "the function was undefined at VA" and

"VA occurred at the zeros of the denominator," I encouraged students to compare the functions $K(x) = \frac{x^2 - 1}{x + 1}$, and $a(x) = \frac{3x - 1}{x + 1}$. I also decided to invoke three types of representations to help students clarify the pitfalls that could arise from only using the algebraic methods or the graphing method using a graphing calculator without paying attention to the deeper structures of these functions. As such, students were asked to work first independently, and then as a group to explore the behavior of functions $K(x) = \frac{x^2 - 1}{x + 1}$ and $K(x) = x - 1$ at x = -1, first without a calculator. Then, they were allowed to use a graphing calculator, to graph and to 'zoom in' and then to explain what they saw. Students were further asked to compare and contrast between the function behaviors of K*(x)*, and $a(x) = \frac{3x - 1}{x + 1}$, at x = -1. This activity lead to a common consensus that a function $f(x) = \frac{p(x)}{q(x)}$ will have a VA at $x = a$, if $p(a) = 0$ and $q(a) \neq 0$. Later a variety of functions such as $m(x) = \frac{2x^2 + 7x - 4}{x^2 + x - 2}$, $f(x) = \frac{3x + 2}{9x^2 - 1}$, $t(x) = \frac{2x^3 - 5x^2 - 2x + 5}{2x^2 + 5x + 3}$ were examined for an in-depth analysis of different properties of different types of asymptotes and function behaviors around the asymptotes.

Instances of spontaneous dealings were invoked by student curiosity on what would happen if the degree of the numerator was larger than the degree of the denominator and what if the degree of the numerator was 2 or more degrees higher than the degree of denominator. These curiosities stimulated the discussions of oblique and non-linear asymptotes. To reveal another example, once students realized that factoring and canceling common factors were the main activities during the identification of holes and vertical asymptotes (VA), I asked students to solve a problem described by a table of values below. I was simply curious on what students might come up with as a consequence of this particular problem. The problem stated that for the function *V(x)*, the denominator was $11x - 4$. By observing the given table of values, what can you say about the behavior of *V(x)* at or around $x = \frac{4}{11}$? Note that $\frac{4}{11} \approx .364$.

This problem incited cognitive conflict in students that lead to some prime realizations. While they narrowed down the possibilities to be either a hole with finite limit or a vertical asymptote with infinite limit, the table of values clearly promoted some discussion. Even though the function appeared to approach infinities from either side of 4/11, as observed from the table of vales, the function value at this point appeared to exist. While students curiously perused how this could be possible, consensus were formed except for exact value x = 4/11, the function will remain defined. These discussions lead to the realization that it was important to always use exact value to discriminate between a hole and a vertical asymptote.

To help students understand the concept of infinite limit I encouraged them to observe the connections between infinite limit and the asymptotic property of the function. To help them recognize the occurrence of infinite limit, I encouraged them to inspect the function value at the point where limit was computed. Students realized that corresponding to the undefined form infinite limit existed. The next issue was to identify the direction in which the function was approaching infinity. One of the problems discussed to help students realize various possibilities was to ask them to discuss and respond to the reasoning behind an imaginary peer's – Mr.

Magoo's – argument while solving problems $\lim_{x\to 2^+}\frac{5x-9}{x-2}$, and $\lim_{x\to 2^-}\frac{5x-9}{x-2}$. Mr. Magoo found *f(3) = 6,* a positive number, and therefore concluded that $\lim_{x\to 2^+}\frac{5x-9}{x-2}=\infty$. Similarly, he concluded that *as* $x \to 2^-$,since *f(1) = -4/-1 = 4,* positive and therefore, $\lim_{x\to 2^-}\frac{5x-9}{x-2}=\infty$. Analyzing problems of this type helped students to see that while choosing to compute function values to tell the direction in which the function was progressing without bound, it is important to always check values "close enough" in addition to computing function values for at least two close enough points before making a conclusion.

While computing limit at infinity, by observing what would happen to each of the terms in the numerator and the denominator of the function as x approached infinities, students were able to infer its implications on the entire function value. They eventually made the observation that what was observed through the step by step examination of function terms connected consistently with the rules that they were familiar with as to comparing the degrees of the numerator and the denominator while computing limits at infinity. As to the discussion of the concept of continuity, within the realm of the time that was left, among other things students were able to make observations as to the different types of discontinuities that contributed to the occurrence of vertical asymptotes and holes.

Conclusion and Discussion

During the teaching experiment, I was mindful about students' previous concept images and how they could interfere with acquiring proper understanding of the concept definition. Drawing from the theory of concept images and concept definition I believed some level of balance between the concept image and the concept definition could be achieved through instructional activities that highlighted the importance active learning via social interaction and group work. This allows students the opportunity to re-examine and re-configure their incomplete conceptions by realizing how the concept applies and work in diverse problem situations.

I realize that student's previous concept images of rational numbers impeded their understanding of rational functions and their properties. This was caused by a limited perspective of rational number which led students believe that rational functions cannot have discontinuities or asymptotes. Thus, from the beginning of the discussion of rational functions and their asymptotes students seemed to have an unresolved disconnect of ideas. Students' conceptual understanding of asymptotes was modified by actively challenging their previous concept images of *invisible lines*, that were *just approached, but never reached* by the graph of the function This was accomplished mainly by reviewing, deconstructing, and amending the textbook definition of asymptotes and by trying to align it with a wide variety of functions.

As a result students were able to make connections between the concepts of limits and asymptotes in a more meaningful manner. They were also able to compute limits without the aid of a graphing calculator by visualizing the behavior of the graph at the point of calculation of limit. Thus, students seemed to have attained certain level of flexibility in the manner in which they think through limits and continuity in connection with function's asymptotic properties.

I believe that as a result of the transaction of the teaching experiment, students seemed to realized that mathematic is more than just by-hearting a bunch of rules and gaining understanding of calculus concepts is a lot more than simply being able to calculate the derivatives and just be proficient in performing different types of integration by simply applying rules.

The Relationship Between Learner Characteristics and Learning Outcomes in a Revised First-Semester Calculus Course

Jason Samuels
City University of New York
jsamuels@bmcc.cuny.edu

There is a long record of student difficulty in calculus. Previous research has suggested that calculus students may benefit from instruction that emphasizes technology, the graphical representation, and the notion of local linearity. For this study, the researcher revised the curriculum of first-semester calculus to incorporate these three elements. For 28 students taking the course, the relationship between several learner characteristics (representation translation proficiency, prior knowledge of rate, prior knowledge of function, spatial ability, and representational preference) and calculus proficiency was assessed. Results showed that the vast majority of students achieved high calculus proficiency, and that the first four characteristics had a relationship with calculus learning outcomes, but representational preference did not. Further, some students revised incorrect prior knowledge.

Introduction

This study was inspired by a history of student difficulties in calculus and innovation in response to those difficulties. A significant body of research has addressed student difficulties and common misconceptions in calculus (Orton, 1983d, 1983i). Researchers and educators have suggested, used and assessed approaches involving a revised syllabus (Heid 1988), increased visualization (Hughes-Hallet, 1991), and technology such as Computer Algebra Systems (CAS) (Kendal & Stacey, 2001). Little is known about the impact of learner characteristics on learning outcomes for calculus students. In this study, a revised curriculum for first semester calculus was constructed which emphasized technology, visualization and the notion of local linearity. The aim was to assess the impact of various learner characteristics on eventual calculus proficiency for students in such a course.

Background

Previous research into student difficulties in calculus has addressed student conceptions and misconceptions of limits (Oehrtman, 2002; Tall, 1992; Bezuidenhout, 2001a), of the derivative (Ubuz, 2007; Bezuidenhout 2001b), and of the integral (Bezuidenhout & Olivier, 2000; Orton, 1983i). The most intransigent of the difficulties occur with limits (Tall & Vinner 1981; Cottrill et al., 1996). Tall (1991) defined a cognitive root to be a unit of knowledge which is a meaningful part of prior knowledge and allows for further theoretical development, and he referred to local linearity as the cognitive root of the derivative (Tall, 1992). Several studies have observed that students can successfully learn the derivative using local linearity instead of limits (Tall, 1986; Maschietto, 2002).

Mathematical situations may be represented in symbolic, graphical, numerical, and verbal ways (Hughes-Hallet, 1991). It is important for students to be able to use each of these representations, and to translate between them (Tall, 1991). There are specific problem-solving benefits to the graphical representation (Hershkowitz & Kieran, 2001; Larkin & Simon, 1987). In particular, more frequent use of visual methods has been associated with higher performance in calculus (Haciomeroglu et al., 2010).

Some research has focused on preconditions for success learning calculus. The importance of prior knowledge of rate (Pustejovsky, 1999) and of function (Tall, 1997) has been noted.

Translation between representations has been adopted into a calculus assessment framework by Kendal & Stacey (2003), but not examined as prior knowledge. Results have been mixed regarding the role of learner characteristics such as mathematical representation preference or spatial ability (Presmeg, 1985; Bektasli, 2006).

A shift away from procedure-driven instruction and toward broader concept-driven instruction is supported by research in psychology (Chen, 1999) and mathematics education (Rittle-Johnson & Alibali, 1999). In calculus, traditional instruction focuses on execution of computations which can now be done with a CAS or other mathematical software (Tall, 1997). Researchers and educators have used, studied, and recommended calculus instruction emphasizing visualization (Hughes-Hallet, 1991), visualization with custom software (Tall, 1986), or CAS (Kendal & Stacey, 2001). For example, Hahkioniemi (2004) suggested that students use the visual representation to intuit differentiation rules.

Java applets and similar computer applications for mathematics instruction ("mathlets") have led to improved learning outcomes in mathematics education (Kidron et al., 2001; Heath, 2002). A mathlet is a small platform-independent application, typically interfaced through a web browser, offering interactive tools to explore a particular mathematics topic. Prior research has identified three main reasons for the potential positive impact of applets throughout mathematics education, and particularly in calculus. First, dynamic interaction is beneficial to the learner (Arcavi & Hadas, 2000); second, lack of dissemination and other logistical difficulties have, in the past, been obstacles to instructional change, but this is not a problem with applets because they can be accessed for free on the internet (Hohenwarter & Preiner, 2007); and third, mathlets are easy to use (Heath, 2002).

Research Question

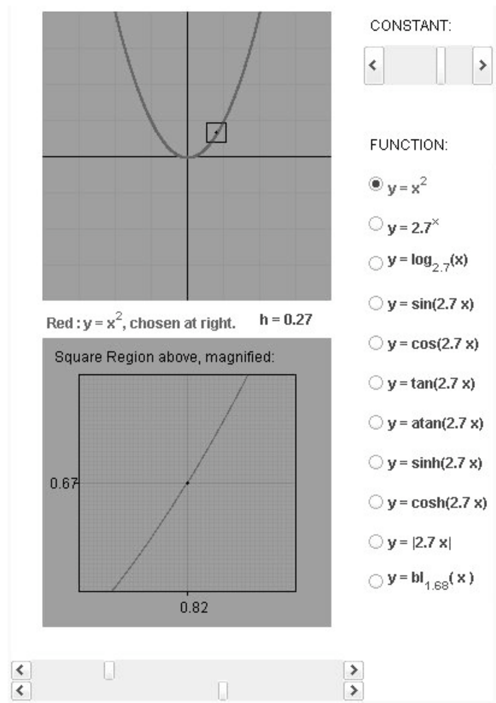
Research has shown that there are several advantages associated with using technology and visualization to teach first semester calculus. However, very few studies have considered the outcomes when a calculus course is reorganized around the notion of local linearity. Further, little is known about how students' different learner characteristics might impact their ability to benefit from this approach. Therefore, this study investigated whether there was a relationship between the learner characteristics of prior knowledge of rate, prior knowledge of function, spatial ability, representation preference, and proficiency translating between representations at the beginning of the semester and the achievement of proficiency in calculus by students by the end of a first semester calculus course which emphasized technology, visualization, and introduced the derivative via the notion of local linearity.

Procedures

The subjects were 28 students enrolled in a first-semester calculus course. Several sections were offered by the college, and students had no prior knowledge of the study, so a selection bias was unlikely. The site of the study was a large urban community college. The instructor was the researcher, who taught one calculus section.

The curriculum for the class was revised to incorporate technology, promote visualization, utilize the notion of local linearity, and delay the introduction of limits. Nine labs, each of which consisted of a mathlet and an activity sheet, were integrated into the course. Lab reports were collected as homework assignments. Students were introduced to local linearity in lab #3, which involved the local linearity mathlet designed by the researcher, displayed in Figure 1 below. The upper window displays the graph of the function selected, and the bottom window displays a small region of the graph. One slider allows the student to change the x-value at the center of the region, and the other slider allows the student to change the half-width *h* of that region. When the function is differentiable at that x-value, under sufficient magnification (sufficiently small *h*) a nearly straight line is graphed in the lower window. The last two choices for *f(x)* include points of non-differentiability. Therefore the introduction students received to the derivative at a point was graphical, as was the subsequent introduction to the derivative as a function. Students thereafter learned symbolic differentiation techniques. Formal limits were covered at the end of the semester.

Figure 1. A screenshot of the local linearity mathlet designed by the researcher



Data on spatial ability, representation preference, prior knowledge of rate and function, and proficiency translating between representations were collected at the beginning of the semester. Spatial ability and representation preference were assessed using instruments from Guay (1976) and Presmeg (1985), respectively, which have documented reliability and validity.

All other assessment followed frameworks constructed by the researcher. The instruments to assess prior knowledge of rate and function and proficiency translating between representations were constructed by the researcher and expert-validated for this study. Prior knowledge of rate and function were each assessed in the four mathematical representations (symbolic, graphical, numerical, verbal), and representation translation was assessed in 8 combinations (from symbolic to graphical or numerical; from graphical to verbal or numerical; from verbal to symbolic, graphical or numerical; and from numerical to graphical) using typical algebra and precalculus exercises assigned at the beginning of the semester.

The framework for calculus assessment was inspired by elements from Maschietto (2002), who used epistemological, cognitive and didactic considerations, Zandieh (2000), who divided comprehension of the derivative into 3 stages, and Kendal & Stacey (2003), who focused on multiple representations in their assessment. Calculus content was categorized according to topic and mathematical representation in the following way: find limits symbolically, graphically, and numerically; state the definition of the derivative symbolically (limit definition), graphically (slope of the graph, slope of the tangent line, slope indicated after magnifying the graph) and verbally (instantaneous rate); find the derivative at a point symbolically (calculate f '(a)), graphically (draw the tangent line, estimate from graph), numerically (estimate from a table), and verbally (calculate a rate in a word problem); find the derivative as a function symbolically (differentiation techniques) and graphically (graph the derivative given the graph of the function); determine non-differentiability symbolically and graphically; solve applications represented symbolically (find the slope or equation of the tangent line, find critical points or optimize a function), and verbally (solve contextual problems such as maximizing profit). Data on learning outcomes were collected during exams and other assignments throughout the semester using expert-validated items, as well as from three task-based semi-structured interviews during the semester. Each unit of student work was categorized and graded for proficiency on a scale from 0 to 4. A score of 3 indicated understanding or a solution that was nearly complete, or complete with several minor errors. A score of 3 or greater reflected high proficiency, and less than 3 reflected low proficiency. Calculus knowledge data were collected throughout the semester, and for each unit of the rubric, the highest level achieved by the student was the assigned score.

Results

Students generally developed a robust conception of the derivative by the end of the course. Overall, 21 students (75%) exhibited high proficiency in learning outcomes collectively. More than 70% of the students were highly proficient in 15 of the 18 rubric categories, including a robust conception of the derivative (in multiple representations and contexts), finding the tangent line (graphically and symbolically), finding the derivative (at a point or as a function, either symbolically or graphically), non-differentiability, symbolic differentiation techniques, and optimization. The other 3 rubric categories all involved limits.

The relationships between learner characteristics and derivative proficiency (as measured by an average of the rubric unit scores) are presented in Table 1.

Table 1. Derivative proficiency achieved by initial student learner characteristic (n=28)

Learner Characteristic	*Initial Level*	*Derivative Proficiency Achieved*	
		High (3.0-4.0)	Low (0.0-2.9)
Representation translation proficiency	High (3.0-4.0)	21	1
	Low (0.0-2.9)	0	6
Prior knowledge of rate	High (3.0-4.0)	20	1
	Low (0.0-2.9)	1	6
Prior knowledge of function	High (3.0-4.0)	12	0
	Low (0.0-2.9)	9	7
Spatial ability	High (15-24)	10	0
	Medium (10-14)	6	4
	Low (0-9)	3	3
Mathematics Representation Preference	Balanced or visual (-3 to 12)	8	1
	Slightly non-visual (-6 to -4)	7	2
	Very non-visual (-12 to -7)	5	2

There was a strong link between representation translation and calculus outcomes. Most students (22) exhibited high proficiency in translating between representations. Of those 22, 21

(95%) displayed high derivative proficiency. Of the 6 with low representation translation proficiency, 0 displayed high derivative proficiency.

There was a clear link between prior knowledge of rate and of function and calculus proficiency. Of the 21 students with high prior knowledge of rate, 20 (95%) achieved high derivative proficiency. Of 7 with low prior knowledge of rate, only 1 (14%) achieved high derivative proficiency. All 12 students with high prior knowledge of function demonstrated high derivative proficiency. Of 16 with low prior knowledge of function, 9 (56%) demonstrated high derivative proficiency.

All 10 (100%) students with high spatial ability demonstrated high calculus proficiency. Of the 10 students with medium spatial ability, 6 (60%) demonstrated high calculus proficiency, and of the 6 students with low spatial ability, 3 (50%) demonstrated high calculus proficiency.

Of the 9 students with a visual or balanced mathematical representation preference, 8 (89%) demonstrated high calculus proficiency. Of the 9 students with a slightly non-visual preference, 7 (78%) demonstrated high calculus proficiency. Of the 7 students with a very non-visual preference, 5 (71%) demonstrated high calculus proficiency.

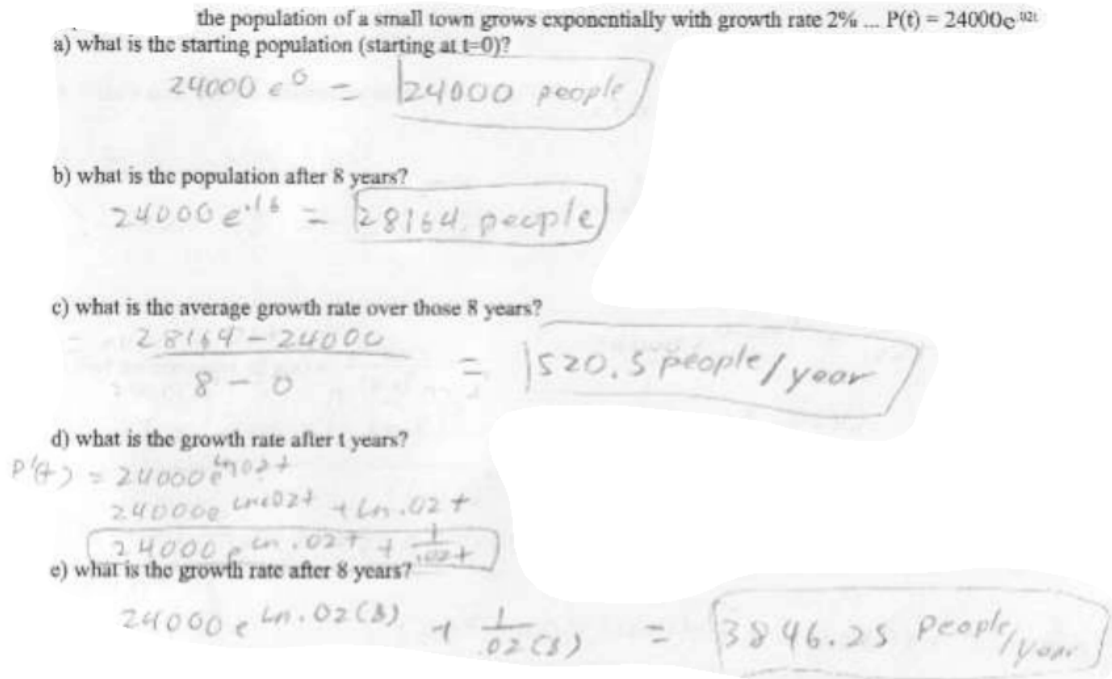
Although representation preference did not have a strong impact on student calculus achievement, some students with a high preference for visual representations demonstrated a very high level of enthusiasm for the course. One student called it his “favorite mathematics class ever.” Another used the mathlets to teach calculus to his friends. He also said “this calculus course has made me more interested in math” and as a result he decided to take more mathematics classes in the future.

Some students revised incorrect prior knowledge during the course. For example, one student demonstrated low proficiency in prior knowledge for distinguishing between average and instantaneous rates. He was asked to solve the following problem:

> The manager of a furniture factory finds that it costs $2200 to manufacture 100 chairs in one day and $4800 to produce 300 chairs in a day. Express the costs as a function of the number of chairs produced, assuming that it is linear. Then sketch the graph. What is the slope of the function and what does it represent?

He wrote, “f(c)=22c or f(c)=16c It first starts off high at 22 dollars a chair then at 300 drops to 16 dollars a chair.” He incorrectly calculated slope as ${}^{y}/_{x}$ determined at each point. After instruction on the derivative, however, the student demonstrated proficiency in making that distinction, as well as in symbolically calculating an instantaneous rate both at a point and as a function (with a minor error), as seen in Figure 2.

Figure 2. Work by one student on a problem about average and instantaneous rate



Another student misunderstood the concept of instantaneous rates given a graph or table of values at the beginning of the course. He also calculated $^{y}/_{x}$, and he asked about using $^{y}/_{x}$ to calculate the slope during a class session. On an early assignment, he wrote, "There are a few things I am not completely clear on: The slope of the point is rise over run, meaning y value over x value…?" Later in the course, he properly distinguished between them, as in the following interview excerpt:

Interviewer: Here's a graph, here are two points on the graph. I'm going to draw this line and take the slope. Is that a derivative?

Student: That is the average [slope].

Interviewer: Oh that's the average. If that's not the derivative then give me an example of a slope which is a derivative.

Student: Take this point for example. Zoom in on it and it becomes like a straight line. The slope would be like that.

Discussion

Three-quarters of the students in this first-semester calculus course, which emphasized technology, visualization, and local linearity, developed high calculus proficiency by the end of the semester. The high level of proficiency achieved by most of the students in this study deserves attention when contrasted with the sobering fact that nationwide half of students taking calculus in college fail (Tall, 1992). Although different initial learner characteristics were associated with varying outcomes, the prevailing result was one of overall high achievement. This finding alone makes the revised calculus curriculum at the heart of this study, and its elements of technology, visualization, and local linearity, worthy of further research.

Four of the five learner characteristics measured in this study were strongly associated with derivative proficiency. The strongest predictors were prior knowledge of rate and representation translation; for each indicator a high score almost guaranteed (over 90%) high calculus proficiency, whereas a low score made low calculus proficiency very likely (over 80%). The importance of prior knowledge of rate is consistent with the findings of Pustejovsky (1999), who used three case studies to conclude that prior knowledge of rate was essential for understanding the derivative. It follows from common sense that understanding rate in the linear case is a necessary precursor to understanding rate in the non-linear case. Further, if students cannot achieve understanding of rate in the simpler linear case, it is unlikely they will learn it in the more advanced non-linear case.

While spatial ability and prior knowledge of function were associated with achieving high derivative proficiency, low or medium spatial ability or low prior knowledge of function did not preclude achieving high derivative proficiency. Notably, representation preference did not have a strong impact on student calculus performance overall; there was almost no difference in rates of high calculus proficiency relative to mathematical representation preference. These are noteworthy outcomes in a calculus class in which graphs were the prime vehicle through which the derivative was introduced. The higher privileging of the visual representation, relative to traditional calculus instruction, did not seem to disadvantage students who were less facile with that representation.

Haciomeroglu et al. (2010) found that a preference for visual methods in solving calculus problems at the end of the semester was associated with higher achievement in the course. The current study found that most students in a calculus class that emphasized visual methods demonstrated high calculus proficiency by the end of the course. This was true even for students who entered without high spatial ability and without a preference for the visual representation. This result strongly supports the inclusion of visual representations in calculus instruction, in particular as part of the curriculum described in this study.

Students in this study revised incorrect prior notions on topics that were related to course content, such as average versus instantaneous rates. This counters the notion that knowledge, once inculcated, is immutable. Rather, acquired knowledge should not be considered static. Thus it is important to find an instructional path which simultaneously delivers new knowledge while enhancing prior knowledge. Some studies have looked at the possibilities for instruction in constant and non-constant rates of change before calculus. Five-year-olds have shown the ability to distinguish between linear and non-linear situations by attending to rate (Ebersbach et al., 2010), and middle school students successfully encountered early calculus concepts with an example of changing rate in kinetics (Barger & McCoy, 2010). The alignment of central mathematical themes and cognitive roots for advanced mathematical ideas, such as rate and local linearity in calculus, suggests a powerful way to organize curricula which encourages students to revisit a theme in courses of increasing sophistication, refine their conceptions, and build meaningful networks rich with connections between fundamental mathematical ideas.

MATHEMATICAL AND NON-MATHEMATICAL UNIVERSITY STUDENTS' PROVING DIFFICULTIES

Annie Selden
New Mexico State University
js9484@usit.net

John Selden
New Mexico State University

This paper discusses university students' mathematical and non-mathematical proving difficulties. A total of forty-one difficulties have been observed and organized into nine categories. Of these difficulties, twenty-seven are briefly described below. These observations come from several years of teaching an experimental proving course to beginning graduate and advanced undergraduate mathematics students and from teaching an experimental voluntary proving supplement to an undergraduate real analysis course. We believe that discussing and categorizing these difficulties will lead to a greater understanding of students' thinking with regard to proof and to future research.

In this paper, we discuss and categorize students' difficulties that were observed and documented over several years in two whole class teaching experiments that emphasized active student participation in the construction of proofs.

Research Settings

The settings in which we observed students' proving difficulties were: (1) a course on proof construction designed to improve the proving skills of beginning graduate and advanced undergraduate mathematics students (hereafter referred to as the "proofs course"), and (2) a voluntary proving supplement to an undergraduate real analysis class (hereafter referred to as the "supplement").

In the proofs course, the students were given self-contained notes consisting of statements of theorems, definitions, and requests for examples, but no proofs. The students constructed their proofs at home and presented them in class. The proofs were then critiqued, sometimes extensively, and additionally suggestions for improvements in the notation used and the style of writing were given. There were no formal lectures, and all comments and conversations were based solely on students' work. Extended comments might occasionally turn into mini-lectures. The specific topics covered were of less importance than giving students opportunities to experience as many different types of proofs as possible and having them develop beneficial ways of reasoning. (For a detailed description of the course, see Selden, McKee, & Selden, 2010.)

The supplement was taught at the invitation of an undergraduate real analysis teacher because her students were having difficulty constructing proofs, because she did not have sufficient time to both cover the content and to work on students' proving as much as she would have liked, and because she was familiar with the above proofs course. Each week, one proof problem was selected or created to "resemble in construction" an assigned homework proof problem that the real analysis teacher intended to grade in detail, and that could be improved subsequently and resubmitted for additional credit. The supplement proof problem could be solved using actions similar to those useful in proving the corresponding assigned homework proof problem. However, the supplement proof problem was *not* a template problem, and "on the surface" would often not resemble the assigned proof problem.

In the 75-minute supplement period, the students co-constructed the proofs at the blackboard with the facilitation and encouragement of the supplement instructors. First the students would co-construct the *formal-rhetorical* part of the proof (Selden & Selden, 2009). This consisted of first writing the hypotheses at the beginning of their proof. Then, leaving a space for the body of the proof, the students would write the conclusion at the end of their nascent proof. Next students would unpack the conclusion and find and write the relevant definitions, such as that of sequence convergence, on the side board that had been set aside for "scratch work." Then the students would change the notation in the definition to "match" that of the theorem to be proved. They would then examine this definition to see where to start and end the body of the proof. For example, if the proof problem were one of showing a sequence $\{a_n\}_{n=1}^{\infty}$ converges to A, they would then write "Let $\varepsilon > 0$" immediately after the hypotheses, leave a space for the determination of N, write "Let $n \geq N$," leave another space, and finally write "Then $|a_n - A| < \varepsilon$" prior to the previously written conclusion at the bottom of their nascent proof. This brought them to the *problem-centered* part of the proof (Selden & Selden, 2009), where some "exploration" or "brainstorming" on the side board would ensue. The entire co-construction process, and accompanying discussions, was a slow one – so slow that only one theorem was proved and discussed in detail in each supplement class period. Finally, a pre-prepared written description of anticipated proving actions (which was usually three or four times as long as the final written proof), would be distributed. (For a detailed description of the supplement, see McKee, Savic, Selden, & Selden, 2010).

Theoretical Background for the Teaching

The teaching for both the proofs course and the supplement was informed by our theory of actions in the proving process and by our division of proofs into their formal-rhetorical and problem-centered parts (Selden & Selden, 2009). We see much of the proving process as a sequence of mental and physical actions, such as writing or thinking a line in a proof, drawing or visualizing a diagram, reflecting on the results of earlier actions, or trying to remember an example. As a person gains experience, much of proof construction appears to be separable into sequences of small parts, consisting of recognizing a situation and taking a mental or physical action. Actions which once may have required a conscious warrant can become automatically linked to triggering situations. We view such small, automated situation-action pairs as persistent mental structures that we have called *behavioral schemas* (Selden, McKee, & Selden, 2010). Such behavioral schemas are a form of procedural knowledge, that is, of knowing how to do something, as well as of "knowing *to* act in the moment" (Mason and Spence, 1999). We see behavioral schemas as very flexible in their implementation. They are not parts of fixed sequences that one might regard as procedures or as the implementation of algorithms. To acquire a beneficial schema, a person should actually carry out the appropriate action correctly a number of times (i.e., practice it) – not just understand its appropriateness. In our teaching, we provided students a variety of proving opportunities so they could acquire beneficial proving schemas. Changing a detrimental behavioral schema requires similar, perhaps longer, practice.

Because the students presented their work in the proofs course and because they co-constructed their proofs in the supplement, we had considerable opportunity to observe their actions. In addition, all classes were video-taped and subsequently analyzed to inform our subsequent teaching, as well as to make more general observations, such as those regarding students' proving difficulties.

Methods of Data Collection

The results reported here are part of a much larger study. Data were collected from 7 iterations of the proofs course beginning Fall 2007. Each semester between four and nine students were enrolled in the course. All class meetings were videotaped and field notes were taken by a graduate research assistant. These videos were viewed and analyzed by the authors and one or two graduate assistants the following day in order to determine what to do in the next class meeting, and interesting observations were noted so that similar instances could be watched for in future. These planning sessions were also videotaped and notes were taken by the first author. Individual tutoring sessions conducted by the second author were also videotaped. Take-home pretest, take-home and in-class final examinations, and student "scratch work" were collected in the proofs course. All this was done in the spirit of naturalistic inquiry (Lincoln & Guba, 1985) and to inform the future design of the course. The authors and the graduate assistants reanalyzed the data to confirm, elaborate, or adjust our earlier observations regarding students' actions and difficulties with proving and discussed these until we agreed on the accuracy of the observations.

In addition, data were collected from three iterations of the supplement beginning in Fall 2009 and these included: videotapes and field notes taken by a graduate research assistant, class homework and tests collected by the real analysis teacher, and observations on proving difficulties noted by the first author. The videotapes were viewed and discussed the following day to see how to design the next supplement class, and students' proving difficulties were observed and later discussed and categorized by the authors of this paper until they reached agreement. Some recurrent difficulties were observed in both the proofs course and the supplement.

Results: Categories of Students' Proving Difficulties

Although undergraduate students' proving difficulties have been observed by a number of researchers (e.g., Moore, 1994; Selden & Selden, 2003), we believe this is the first attempt to categorize and document as many of them as possible. Below we describe each category and give several examples of each. Some categories may overlap and this will be noted. When other researchers have reported similar difficulties in the literature, this will also be noted.

Non-mathematical Difficulties that Influence One's Ability to Prove

These came as a surprise to us and were noted in the supplement where we had ample opportunity to observe students in the process of proving theorems that were new to them. Examples include:

(1) There were students who were unable to copy a definition correctly onto the blackboard from the book or their notes while they were doing "scratchwork" or "brainstorming." This is important as missing even one word or phrase such as "for every" in a definition can lead to misunderstanding.

(2) There were students, who as spokespersons for their student groups, were unable to articulate notation or mathematical terms when reading or explaining a proof they had just constructed.

(3) There were students who had trouble adapting the letters (symbols) in a definition or previous theorem to the statement of a current theorem that they were attempting to

prove or use (in a line of their proof). This was merely a change in the symbolism; there was no change in the meaning. They merely needed to adjust the symbolism to fit the current context. Yet the students apparently found it difficult to go from one context to another. An example was using the definition of continuity given in terms of a function *f* to prove a theorem about a function $f \circ g$. Another is the real analysis student who used the letter *n* in his proof, and then found a relevant result in his textbook, and assumed (wrongly) that the letter *n* in the textbook theorem was the same as the one in the partially completed proof. We consider this, in part, as a difficulty with substitution – an area that has not been well researched.

Using Logic to Structure Proofs

It has been noted that university students have trouble using logic to structure their proofs (e.g., Moore, 1994; Selden & Selden, 2003). Indeed, a few transition-to-proof course textbooks pay special attention to this (e.g, Velleman, 1994, Chapter 3). By structuring proofs, we mean more than the usual discussion in such textbooks of how to begin and end direct proofs, contradiction proofs, contrapositve proofs, and mathematical induction proofs.

The extent and variety of these structuring difficulties seems not to have been fully considered and documented. Some situations involve making rather fine distinctions that probably do not need to be made in everyday conversation, and as such, may need special attention when teaching beginning university students. Examples include:

(1) Not knowing, when a situation with several possibilities occurs, that one can usefully consider cases, that the cases must cover all possibilities, and that the cases may overlap. A simple instance is considering cases when $x \in A \cup B$.

(2) Not understanding the distinction between *using* a definition to prove a statement (e.g., using the fact that a given sequence converges) versus proving a mathematical object *satisfies* a definition (e.g., showing that a particular sequence converges) is a difficult distinction to grasp and harder yet to implement. This was especially hard when our students had to make this distinction within a single proof, for example, in attempting to prove the product of two convergent sequences is convergent. Making this distinction involves knowing that a definition is an “if and only if” statement and keeping straight when and how to use the “if” part, in contrast to when and how to use the “only if” part.

(3) In a proof by mathematical induction, not knowing that one should start the induction step of what is to be proved with k+1 instead of k (especially when the statement of the theorem includes a “for all”), and only later using the induction hypothesis for k. This was observed more than once when a student in our proofs class attempted to prove that polynomials are continuous. Typically, the student began with an arbitrary polynomial of degree k, added to it a term of the form $a_{k+1}x^{k+1}$, and then proceeded to use the induction hypothesis. By doing this, the student had *not* proved that an arbitrary polynomial of degree k+1 is continuous, but rather only that a polynomial of this special form is continuous. The student might better have begun with an arbitrary polynomial of degree k+1; separated it into two parts, the term $a_{k+1}x^{k+1}$and the rest, which is a polynomial of degree k; applied the induction hypothesis to the latter; and finally applied the known (to the student) facts that sums and products of continuous functions are continuous, that a constant times a continuous function is continuous, and that polynomials of the form x^n are continuous.

"Metacognitive Knowledge/Actions"

Under this category, we have placed difficulties that seem to stem from the enactment of detrimental behavioral schemas or the lack of enactment of helpful behavioral schemas. The later might also be seen as a lack of strategic knowledge (Weber, 2001). Examples include:

(1) Knowing, or not knowing, that one can just "pick" an element that is known to exist (especially from an infinite set) instead of attempting to construct such an element. It would suffice to observe that such an element exists and give it a name, such as x_1.

(2) Focusing too soon on the hypotheses of a theorem to be proved, instead of first focusing on, and unpacking, the conclusion to see what is to be proved. We have documented in detail the case of Willy who did this for a theorem in topology (Selden, McKee, & Selden, 2010). We have observed this particular detrimental behavioral schema enacted many times by many students.

(3) Knowing, or not knowing, how to prove a compound element, or entity, is in a set. This was documented in detail and occurred when Sofia was attempting to prove the relative topology on a subset of a topological space is indeed a topology (Selden, McKee, & Selden, 2010).

(4) Knowing, or not knowing, when proving or disproving two groups (such as **N** and **Q**) are isomorphic, that one should first look for properties preserved by isomorphisms, rather than trying to find a bijection between the two groups and then attempting to show the operation is preserved (Weber & Alcock, 2004).

Going Outside of the "Proof Genre"

Students may have good ideas for a proof, but may not yet have mastered the art of writing proofs in the way their professors expect. A similar observation has been made by Mamona-Downs and Downs (2009). Examples include:

(1) Having a propensity to write definitions (that can be found outside the proof) into the proof. For example, some students wrote the entire definition for the continuity of a function into their proofs, instead of simply saying something like "By continuity of *g*, we have …".

(2) Writing directions to oneself, such as "I am now going to try to show that ..." or "We have to show that ..." in a (not exceptionally long) proof.

(3) Using informal language in a proof or using a word or concept that has not yet been formally defined. This occurred when students used function notation, such as $f^{-1}(x)=y$, instead of the ordered pair notation, before having proved that the inverse of the function f is also a function. Dreyfus (1999, p. 88) gave an example of a first-year linear algebra student who was asked to determine whether the following statement was true or false and explain. *If $\{v_1, v_2, v_3, v_4\}$ is a linearly independent set, then $\{v_1, v_2, v_3\}$ is also a linearly independent set.* The student's answer was "True because taking down a vector does not help linear dependence." It is possible the student understood, but the use of "taking down" and "help" points to a lack of linguistic capability.

Conventions of the Mathematical Register

This category has a certain overlap with the above. Examples include:

(1) Not knowing the difference between "minimum" and "minimal."

(2) Knowing how to prove an "if and only if" statement by dividing the proof into two parts, indicating the beginning of one part by "($\rightarrow$)" and the beginning of the other

part by "(⟵)", thus demonstrating a knowledge of "if and only if" at an action level, but later asking about the meaning of "necessary and sufficient."

"Standard" Techniques of Proving

While these may have some overlap with the above mentioned "metacognitive knowledge/actions," one could also think of lacking these as having an "impoverished mathematical toolkit."

(1) Not knowing how to show "at most one" versus "at least one" or how to prove there is a unique object with some property by assuming, say x_1 and x_2, have the property and then showing $x_1 = x_2$.
(2) Not knowing how to use the Axiom of Choice, or which version to use.
(3) Not knowing how to prove "*p* or *q*" by assuming "not *p*" and proving *q*, or alternatively, by assuming "not *q*" and proving *p*.

Notational Difficulties

Using symbols carefully to "say what you mean" and "mean what you say" is not easy for students. Also, knowing when a symbol can be used again in a proof, and when it cannot, takes time to learn.

(1) Not knowing the *n* (or another variable) in a theorem one is trying to use is *not* the same as the *n* in one's proof.
(2) Problems dealing with three levels of abstraction: elements *u*, sets *U*, and families $\mathcal{U}$. For example, a set U can be open, but $\mathcal{U}$ (the topology) cannot be open.
(3) Being confused about when one can "reuse" a variable name. In a real analysis proof, a student used *Q* both for a neighborhood outside the proof (in the definition) and a neighborhood inside the proof.
(4) Not knowing how to avoid the use of indices, especially when the index set in not necessarily countable, or when it would be clearer to write without using indices. An example occurred when a student was trying to use mathematical induction to prove that any finite intersection of open sets is open, given that the intersection of any two open sets is open. The student could have considered an arbitrary family $\mathcal{B}$ of *k*+1 open sets, let $B \in \mathcal{B}$, and noted that $\bigcap \mathcal{B} = (\bigcap (\mathcal{B} \setminus \{B\})) \cap B$ is the intersection of two open sets and applied the induction hypothesis to the former intersection. However, the student used indices and got lost in the notation.
(5) Using the $\in$ and $\subseteq$ symbols interchangeably. This may be a confusion caused by everyday experiences with the use of "in". For example, if one has an aspirin in one's cosmetic bag which is in one's purse, it's OK to say "I have an aspirin in my purse" (Zazkis & Gunn, 1997). Part of students' confusion may also result from instructors using "in" for both "is an element of" and "is contained in."

Knowledge and Use of Quantifiers

That students have problems with quantifiers has been well-documented in the literature. This includes: not understanding that the order of the quantifiers influences the meaning of a statement (Dubinsky & Yiparaki, 2000); having difficulty interpreting implicit quantifers (Selden & Selden, 1995), and knowing the scope of a quantifer (Epp, 2003). We observed:

(1) In general, many students have difficulty with proving universally quantified statements, in which one customarily considers an arbitrary, but fixed, element, as in

□ real analysis proofs. They often wonder why the result has been proved for all elements, such as □, rather than only for the specific arbitrary, but fixed, element selected. Further, students often take a long time to feel comfortable that this is a legitimate method of proof; we have documented this with the case of Mary (Selden, McKee, & Selden, 2010).

The Problem-Solving Aspects of Proving

In an attempt to have students improve the problem-solving aspects of their proving and to have a "rough gauge" of (one dimension of) the difficulty level of proofs in our notes, we devised what we have called Type 1, 2, and 3 theorems (Selden, Selden, & McKee, 2008). How hard a theorem is to prove depends on many factors including a particular student's knowledge base and the method of proof. However, it is often possible, in the context of a given class, to make a judgment of difficulty for most students in the class. So in devising these three types of theorems, we were thinking of the kinds of proofs that our students had most often produced.

(1) A *Type 1 theorem* is one whose proof requires that students have to look for a useful theorem in the course notes. We put such theorems in our notes after it became clear that many students didn't look back over their notes to see if there were any useful theorems they could call on, rather than proceeding directly from the definitions of the concepts involved. For example, we have a theorem in our notes on the boundedness of a continuous function near a fixed number that would be useful in showing that the product of two continuous functions is continuous. However, our students rarely used that theorem and had difficulty proving the product theorem.

(2) A *Type 2 theorem* is one whose proof calls for stating and proving a lemma that is easily articulated and proved. We consider this to be cognitively more difficult than merely looking in the notes for a relevant theorem.

(3) A *Type 3 theorem* calls for stating and proving a lemma that is not easily articulated and proved. Doing this calls for considerable creativity. In our proofs course, *A commutative semigroup with no proper ideals is a group*, is such a theorem. There are two lemmas that would render the proof merely "a little tricky." However, these lemmas were purposefully not included in the notes so students could have the opportunity to discover them.

Discussion

While we do not claim the above nine categories are nonoverlapping or a complete list, we do believe they form a useful start. Also, although we have documented 41 difficulties, we have briefly described just 27 of them to illustrate the categories. We feel this is a beginning that could be helpful both to university and other teachers, as well as to researchers.

Several of the difficulties mentioned above have not been investigated in detail. For example, that simple non-mathematical difficulties can interfere with proving was a complete surprise to us and is open for investigation. Questions one might ask include: How do such difficulties as copying incorrectly directly from one's textbook or notes arise? Is this due to students' inadequate reading comprehension skills? How is it that students have not learned to articlulate (in words) various mathematical symbols? What does this imply about these students' mathematical thinking, if as Sfard (2009) asserted, thinking is just communicating with oneself? What do students think, or vocalize in inner speech when they encounter a mathematical symbol such as $\int_a^b f(x)dx$? What do students do with respect to articulating symbols when presenting their proof attempts for whole class discussion? Do students simply avoid vocalization by saying such things as, "We calculated, or we considered, this" and then point to the symbols? If so, why do they do this?

Another area that has not been investigated concerns structuring proofs. What does it imply about students' understanding of definitions if they do not know, in proving, the difference between *using* a definition of an object to assert a fact and proving an object, such as a function *g*, *satisfies* the definition of continuity. To date, much has been written about students' not knowing that mathematical definitions are analytic (or stipulated) rather than descriptive (e.g., Edwards & Ward, 2004); however, even after knowing this, students seem to have trouble making the much more subtle distinction between using a definition and satisfying a definition.

These are just some of the possible interesting questions that could be investigated.

ASSESSING AFFECT AMONG UPPER ELEMENTARY STUDENTS WHO ARE GIFTED IN MATHEMATICS: VALIDATING THE CHAMBERLIN AFFECTIVE INSTRUMENT FOR MATHEMATICAL PROBLEM SOLVING

Scott A. Chamberlin
University of Wyoming
scott@uwyo.edu

Robert Powers
University of Northern Colorado

The focus of the article is the validation of an instrument to assess gifted students' affect after mathematical problem solving tasks. Participants were 225 students identified by their district as gifted in grades 4-6. The Chamberlin Affective Instrument for Mathematical Problem Solving (CAIMPS) was used to assess feelings, emotions, and dispositions after students solved Model-eliciting Activities (MEAs) in groups of three. Through the use of principal component analysis, it was determined that three factors should be retained. The instrument holds promise because it may be used to assess affect which has implications for identification and curricular adjustments to optimize affect.

Literature Review

Conception of Affect in Mathematics Education

Myriad conceptions of affect appear to exist in mathematics education (Mann, Carmody, Chamberlin, 2011). Hart and Walker (1993), Hoffman (1986) and McLeod and Adams (1989), as examples, have referred to affect in mathematics using words such as motivation, dispositions, emotions, beliefs, and attitudes. Most definitions contain some variation of the aforementioned terms. It is therefore instrumental that one conception of affect be adopted. Anderson and Bourke's (2000) conception of affect is one commonly accepted given its degree of comprehensiveness. Consequently their conception of affect has been used for this research. They refer to affect as comprised of eight sub-components including: anxiety, aspiration, attitude, interest, locus of control, self-efficacy, self-esteem, and value.

Conception of Giftedness in Mathematics

Like the concept of affect, the concept of giftedness is a rather nebulous one. This is the case because countless definitions exist for giftedness and when applied to a discipline, e.g. mathematics, additional definitions seem to be propagated. Nevertheless, the definition of giftedness for this study is based on Krutetskii's (1976) premise that giftedness in mathematics is multifaceted. Through empirical research, Krutetskii found that nine areas of giftedness exist, but it could be argued that more exist. In specific, Krutetskii's nine areas of giftedness are: "the ability to formalize, the ability to generalize mathematical material, the ability to operate with numerals and mathematical symbols, an ability for sequential, properly segmented logical reasoning, an ability to shorten the reasoning process, an ability to reverse a mental process, flexibility of thought, mathematical memory, and an ability for spatial concepts" (pp. 87-88). Typically, students gifted in mathematics have at least one and perhaps more than one area of giftedness in mathematics.

History of Affect

The call to assess affect occurred as early as 1916, when Binet and Simon suggested that efficient cognition is impacted by feelings, emotions, and dispositions. They referred to affect as non-intellectual factors and they mentioned the ability to assess non-intellectual factors in school learning as of paramount importance. They viewed non-intellectual characteristics as equal importance to intellectual characteristics. Binet and Simon further claimed that the development of non-intellectual characteristics was antecedent and prerequisite to the development of intellectual characteristics. They suggested that by neglecting affect, learning conditions may be seriously compromised.

Non-intellectual characteristics then became known as non-cognitive characteristics (Chamberlin, 2010; Messick, 1979). The biggest challenge facing researchers, then and now, is the problem of quantifying a psychological construct. In short, researchers are faced with the question, “How do we measure something that does not readily lend itself to being measured?” Clearly defined concepts such as speed, volume, and mass are much easier to quantify since agreed upon metrics exist, but (psychological) constructs such as interest, attitude, and value do not have agreed upon metrics to quantify the degree of interest, attitude, and value. The question therefore remained, “how are these constructs quantified?”

Binet and Simon (1916) mentioned the significance of non-intellectual characteristics, but it was not until some 55 years later that a reputable instrument was created. In 1970, the National Longitudinal Study of Mathematical Abilities (NLSMA) completed a study conducted on a curriculum developed by the School Mathematics Study Group (Higgins, 1970). Researchers assessed student attitude with the use of 18 scales and the instrument had moderate to strong reliability coefficients (.59 to .85), but validity was not reported in the study. Interestingly, the impact of the instrument itself may not have been as significant as the creation of an instrument designed to assess a non-cognitive component. Two years later, Richardson and Suinn (1972) created the Math Anxiety Rating Scale (MARS) which was designed to assess student anxiety, and it was highly respected in the field of assessment of (mathematics) affect. Reliability coefficients were high for this instrument (.85 to .97) and the instrument’s validity was normed relative to the Differential Aptitude Test.

The aforementioned instruments were created to assess only one component of affect (e.g. attitude or anxiety). Hence, Aiken’s instrument (1974) not only promoted the idea that attitude may be comprised of enjoyment and value, but he actually followed up his theory with an instrument to assess each component. The true impact of the instrument came with the notion that Aiken promoted the theory that affect is multifaceted. Similar to the Richardson and Suinn (1972) instrument, the reliability was moderate to strong (.6 to .85), but the criterion validity of the instrument was questionable (.10 to .40).

The Fennema-Sherman Mathematics Attitude Scale (Fennema & Sherman, 1976), the first one widely used by researchers, was composed of nine scales that are ostensibly separate, but in reality are closely connected to one another. Four scales provide data on student affect and five additional scales provide data on teacher and parent affect. In addition, gender of participant and usefulness of mathematics is a domain. Two contributions arose from the development of this instrument. The first was that gender issues were brought to the fore of mathematics education and the second was that four components of affect were assessed at one time. The somewhat outdated scale was revised and re-validated in 1999 (Forgasz, Leder, & Gardner, 1999).

Only one study can be found that pertains to assessing gifted students’ affect in mathematics. In 1996, Pajares conducted a study on mathematical problem solving of gifted students and he used his self-efficacy instrument that had never been validated with gifted students so the results may be questionable. Despite all of this work, quite literally, no instruments have been created or validated for use with gifted students. Moreover, almost no instruments were created to assess affect during or after mathematical problem solving as most have been created generically to assess affect in mathematics. Consequently, the need for an instrument that has been specifically designed for use with gifted students that focuses on affect and mathematical problem solving would be an asset to the field of mathematics and gifted education.

Regarding affect and mathematics, one question perpetually surfaces which is, 'why does an instrument to assess affect among GT students in mathematics need to be created and subsequently validated?' This is a legitimate question. The responses to this question are threefold. First, affect is one of the most crucial impacts and determinants regarding students' achievement in mathematics (Dettmers et al., 2011; Shores, Shannon, & Smith, 2010). Second, it has been hypothesized that this age level, i.e., grades 4-6, are the most important for the development of long-term attitudes, emotions, and dispositions regarding mathematics (Hart & Walker, 1993). The ramifications therefore of neglecting affect among GT students is that if students develop negative affect towards mathematics in grades 4-6, the most promising mathematics students will be lost to other disciplines. Third, it is the moral imperative of the American educational system to substantially challenge all students, including the most capable students (Sheffield, Chamberlin, Tassle, Mann, & Carmody, 2011). Affect and challenge are intricately intertwined and neglecting such students does not bode well for international ratings of American students in mathematics and it may further have negative ramifications for maximizing mathematical learning in the classroom.

Methods

Mathematical problem solving is the focus of doing mathematics (National Council of Supervisors of Mathematics, 1978; National Council of Teachers of Mathematics, 1980; 1989; 2000). Given the high priority of mathematical problem solving (Chamberlin, 2008), it was determined that an instrument was necessary to monitor student affect after the process.

Participants

Participants in the study came from four elementary and middle schools throughout the inter-mountain region of the United States. There were 225 participants from a potential sample of 250 or a 90% response rate. The respective number of boys and girls in the actual sample is not known because all data were collected anonymously and gender was not recorded as per the schools' requests. However, there is no indication that a gender bias existed among participants because the actual sample appeared similar to the target sample which contained 51% girls and 49% boys.

Identification Procedures

Prior to soliciting schools, the first author investigated the identification procedures to see that similarity existed from district to district. Each school had minimally different identification procedures and they were all aligned with identification procedures consistent with those outlined by the National Association for Gifted Children.

Implementation of Problems

All of the problems implemented were open-ended tasks so they had more than one solution (process) and more than one product as potential responses. Further, students were given no direction regarding what mathematical procedure to use in an attempt to solve the problem. For each task, students were asked to read the newspaper article that accompanied the handout at home the night before the task was implemented and to complete a series of questions designed to create conversation about the topic. On the day of the activity, students met as an entire class, discussed responses to the comprehension questions with the facilitator (i.e., the first author), and read the problem statement. Once the facilitator was assured that all students understood what was asked in the problem statement, students worked with peers in groups of three to solve the problem. Solving the problems and writing up the solutions typically required 50 to 70 minutes so some class periods were extended to accommodate the research protocol. Upon immediate completion of the problem solving task, students were asked to complete the instrument designed to assess affect. This was done in an attempt to garner accurate data regarding student affect during the mathematical problem solving process. Solution discussion followed data collection.

Tasks Used

The tasks used were a special type of mathematical problem solving activity called Model-eliciting Activities (MEAs). To date, the most comprehensive review of MEAs, i.e., their purpose and general characteristics, who and how they were created, some examples, characteristics of student interpretations, four disclaimers, the six principles for design, common misconceptions, and questions about them, is detailed by Lesh, Hoover, Hole, Kelly, & Post (2000). The design principles, explicated in Chamberlin and Moon (2005) and Lesh et al., provide a basis for understanding what comprises all MEAs. At the heart of how MEAs are created are the six principles used to design MEAs. These principles are: the Model-construction principle, the Reality principle, the Self-assessment principle, the Construct Documentation principle, the Construct Shareability and Re-usability principle, and the Effective Prototype principle. The objective in using the six design principles is to increase the likelihood of uniformity in the structure of tasks. The Model-construction principle suggests that all MEAs demand that a mathematical model is constructed to explain the mathematical phenomenon or phenomena. The developed model should have immediate utility and future utility (reusability). The Reality principle does not insure that all tasks are immediately applicable to all students' lives. Instead the Reality principle demands that all tasks demand that students try to make sense of a mathematical situation. The Self-assessment principle suggests that each MEA should have some component that enables students to determine whether or not their response is logical. One question often posed to assess this principle is, "Will students know when they're finished with the problem?" The Construct Documentation principle suggests that each MEA must demand that students document their work. This documentation should closely detail their thinking (especially their mathematizing of the situation). The Construct Shareability and Re-usability principle demands that each MEA must have the construction of a model for it to be an MEA. Moreover, the model should meet the demands of the immediate problem, and as models go, should be able to be used in subsequent, similar mathematical situations. Therefore each model should satisfy an immediate as well as a long-range need. The Effective Prototype principle suggests that each MEA should leave some residue (Skemp, 1982) for future mathematical situations. The Construct Shareability and Re-usability principle demanded that the model is transferrable to future situations. The Effective Prototype principle demands that mathematical concepts learned may be applied to future, non-identical, situations.

Examples of MEAs may be found online at http://crlt.indiana.edu/research/csk.html and at https://engineering.purdue.edu/ENE/Research/SGMM/CASESTUDIESKIDSWEB/index.htm.

The activities used for this research were ones that have traditionally been perceived by teachers as free of or with significantly reduced gender bias. Activities used were: On-time arrival, Track programs for sale, Summer reading, Amusement park, and Track and field teams.

Instrumentation

The Chamberlin Affective Instrument for Mathematical Problem Solving (CAIMPS) was designed for grade 4-6 mathematics students of advanced academic ability. It is important to note that students in the convenience sample were not all identified as gifted in mathematics. Pending identification procedures, some students were simply identified as gifted in general. The 40-item instrument was initially designed to assess Anderson and Bourke's (2000) eight factors of affect with five items comprising each scale. These factors are: anxiety, aspiration, attitude, interest, locus of control, self-efficacy, self-esteem, and value. Respondents were provided with five options regarding how they would respond to each item: strongly agree, agree, undecided, disagree, and strongly disagree.

Results

Validation of the CAIMPS

The statistical procedure employed to investigate the actual number of factors that the CAIMPS would yield was exploratory factor analysis (EFA), a kind of principal component analysis. EFA is a process whereby items are analyzed repeatedly in an attempt to "identify the fewest possible constructs needed to reproduce the original data" (p. 533, Gorsuch, 1997). The number of factors was determined by the Cattell Scree-plot Test (Cattell, 1966). Based on the component factors of the scree, the analysis proceeded to extract three principal components (Stellefson & Hanik, 2008; Tanguma, 2000).

Statistical Procedures Used

A varimax roation method was employed to extract the three principal components (Bauer, Jackson, Skwarchuk, & Zelefsky, 2006). The Keiser-Meyer-Olkin test determined acceptable sampling adequacy (.916), indicating that few common factors were shared in the three factors. Bartlett's test of sphericity confirmed that the data were non-collinear. Based on the items that loaded onto each factor, the researchers identified the three factors as:

- Attitude/value/interest
- Self-esteem/self-efficacy
- Aspiration

Additionally, three items did not load onto these factors. Although each item was intended originally to investigate anxiety, their internal reliability of .519 was not satisfactory enough to identify them as a stand-alone construct and the items were consequently discarded from the analysis. Each factor is described below.

Factor 1: Attitude, value, interest

The first factor is comprised of the items associated with attitude, value, and interest. The construct is comprised of 14 items: 1, 2, 6, 9, 13, 20, 23, 24, 27, 30, 31, 32, 34, and 37. The measure of internal reliability, Cronbach's alpha was very high (α= .918).

Factor 2: Self-esteem, self-efficacy

The second factor is comprised of the items associated with self-esteem and self-efficacy. The construct is comprised of 14 items: 3, 4, 5, 10, 12, 16, 17, 19, 26, 29, 33, 36, 39, and 40. The measure of internal reliability was also high (α=.908).

Factor 3: Aspiration

The third factor is comprised of the items associated with aspiration. The construct is comprised of 8 items: 8, 14, 18, 21, 25, 28, 35, and 38. The Cronbach's alpha is moderately high (α=.805), and certainly within acceptable levels.

Discussion

Implication 1: Use of Instrument

This instrument was designed for specific use with upper elementary and lower middle grade gifted students at the immediate conclusion of an open-ended mathematical problem solving task. Given the diversity of characteristics of the sample, the instrument may be used with a broad range of students as it was validated with students identified as gifted in general. The application of this instrument to classroom settings with gifted students may provide immediate, reliable data regarding students' affect at the conclusion of mathematical problem solving activities.

Implication 2: Use of Instrument for Identification Procedures

This instrument may have particularly strong implications for identifying advanced mathematicians and it may point to prospective success in mathematics. Identification of students who have the greatest likelihood of success in a program is a necessary component in strong identification procedures and affective ratings should be considered in this equation. With initial identification procedures, seeking very high intellect was the only emphasis in GT programs. However, more contemporary beliefs are that multi-modal procedures can bolster and provide more comprehensive data than simply viewing IQ data.

Implication 3: Ease of Ese

Given the relative ease with which this instrument may be implemented, it is noted that teachers of the gifted can have the ability to make immediate changes in an effort to maximize learning. Moreover, this investigation of affect, through the use of an empirically proven instrument, may be used with certainty given data attained.

The implications contribute to GT mathematics students' learning insofar as they are all intended to provide immediate data for teachers to make adjustments to curricular approaches and selections. Moreover, the data secured was designed for assessment of affect with highly open-ended tasks. The positive component to this instrument is that students' affect links directly to their achievement. Negative affective ratings do not insure poor learning, but statistically, they correlate very closely. Similarly, positive affective ratings do not insure the maximization of learning in mathematics, but they set up the pre-conditions for the optimization of learning in mathematics. Fundamentally, affect cannot be intentionally impacted without a cognizance of the level of affect. Moreover, an instrument that reveals affective ratings on problem solving tasks enables teachers to make instructional decisions immediately to positively impact learning environments.

Limitations

The first limitation is that the sample that completed the problem solving activities and the instrument were predominately students identified as gifted in general (not gifted specifically in mathematics). Hence, some students were truly advanced in mathematics and some were simply average ability students in mathematics which is a fairly diverse sample. Second, the method for analyzing data was exploratory factor analysis. Confirmatory factor analysis is often regarded as a more powerful approach to solidifying results and would therefore be the more preferential of the two approaches.

Areas for Future Research

Two areas for future research exist. First, for subsequent data collection procedures, the more specific population of individuals gifted only or at least in mathematics should be explored although this potentially nebulous construct may prove problematic in assessing students. What one may consider gifted in mathematics may not be what another considers gifted in mathematics. Second, some limitations are evident with exploratory factor analysis (EFA). Chief among the concerns is that the process of EFA is just as the name implies…exploratory. Consequently, the revised instrument must be used with a new sample of students with the intent of using Confirmatory Factor Analysis (CFA) to investigate the statistical strength of the instrument.

SELF-EFFICACY, PERFORMANCE, & CALIBRATION IN ADVANCED MATHEMATICS

Joe Champion
Texas A&M University - Corpus Christi
joe.champion@tamucc.edu

This study applied a social cognitive framework to investigate self-efficacy, calibration (accurate feelings of knowing), and exam performance among 195 students in the content courses of a secondary mathematics teaching program. Using structural equation modeling analysis of survey and final exam data, findings suggest high prior performance, strong self-efficacy, and slight overconfidence are most associated with increased exam performance.

A quote attributed to Henry Ford summarizes a key principle in the social cognitive view of learning: "Whether you think that you can or that you can't, you're usually right." This hypothetical relationship between performance and beliefs in one's capabilities hinges on effects of perceived *self-efficacy*, or self-evaluations of one's ability to accomplish given performances under specific constraints (Bandura, 1997). In the context of the undergraduate mathematics coursework of prospective secondary mathematics teachers, Ford's simple axiom about the influence of self-efficacy on success is just one part of multifaceted interactions among experiences, self-beliefs, academic motivation, and performance that can help to explain future teachers' trajectory toward meeting their goals in mathematics.

Research into self-efficacy has established that learners who express high self-efficacy in an academic domain tend to perform better on tasks in the domain than similarly knowledgeable peers who report low self-efficacy (Pajares & Schunk, 2001). More than 1,800 research studies in education have addressed self-efficacy, and results suggest moderate-to-strong positive effects of self-efficacy judgments on performance tasks in domains as diverse as reading comprehension, career choice, and problem-solving in mathematics (Lightsey, 1999). However, there are documented exceptions to this trend (e.g., Klassen, 2006), and some important aspects of mathematics self-efficacy, especially *calibration*, or the accuracy of students' self-efficacy judgments, have received little research attention.

Following a thorough review of literature on mathematics self-efficacy, the dissertation study reported here addresses three aspects of the existing research which suggest further study: (1) the self-efficacy of college students in advanced mathematics courses, (2) the calibration of students' beliefs in their mathematical abilities, and (3) the mathematics self-efficacy of prospective secondary mathematics teachers. The overarching purpose was to investigate the following question:

> *How do self-efficacy and calibration influence the exam performance of students enrolled in the mathematics courses of a secondary teacher preparation program?*

Theoretical Framework

When considered in the complicated context of mathematics content preparation for secondary teachers, a social cognitive conceptual framework can help to explain the level and accuracy of students' self-perceptions of their abilities in advanced mathematics courses.

Social Cognitive Theory and Self-Efficacy

Albert Bandura's social cognitive theory first began as a means for explaining observational learning mechanisms by positing that a *causal triadic reciprocality* exists between individuals' behavior, environmental stimuli, and internal cognitive factors. This approach has since developed into a robust theory increasingly focused on the cognitive and motivational processes supporting metacognition (Schraw, 1998), self-efficacy, and self-regulation among learners as they acquire knowledge and skills. Self-efficacy emerges as a prominent theme; Lightsey (1999) identified over 2500 hundred articles addressing relationships between self-efficacy and achievement.

Social cognitive research considers self-efficacy to be a mediating mechanism in human cognition because self-beliefs in ability act as a filter between prior experiences and subsequent development of abilities within a particular domain. In contrast to self-concept, which refers to more global self-beliefs and personal identity, Pajares and Schunk (2001) summarize the hypothesized direct role self-efficacy plays in the choices people make:

> Self-efficacy beliefs influence the choices people make and the courses of action they pursue. Individuals tend to engage in tasks about which they feel competent and confident and avoid those in which they do not. Efficacy beliefs also help determine how much effort people will expend on an activity, how long they will persevere when confronting obstacles, and how resilient they will be in the face of adverse situations. (p. 241)

Attributed in part to individuals' tendencies to rely heavily on self-efficacy beliefs during difficult tasks (Bandura, 1997), self-efficacy judgments are often better statistical predictors of performance in academic domains than standardized measures of ability or intelligence (Pajares & Kranzler, 1995). In fact, after controlling for instructional factors, path analyses of performance incorporating biographical (e.g., socio-economic status, gender), motivational, and instructional variables, suggest self-efficacy beliefs account for the largest portion of variation in academic performance (Madewell & Shaughnessy, 2003). Though measures of self-efficacy are often useful for predicting performance, strong self-efficacy beliefs may be less connected to success in difficult domains such as mathematics. In particular, developing both strong and accurate self-efficacy beliefs may be foundational to the benefits of self-efficacy in learning mathematics at the level of calculus and above.

Mathematics Self-Efficacy, and Calibration

Sometimes referred to as "feeling-of-knowing accuracy" (Schraw, 1995, p. 326), students' *calibration* (Pajares & Miller, 1994) in self-efficacy ratings is a relatively new area for mathematics education research (e.g., Chen & Zimmerman, 2007) with foundations in experimental psychology and reading education (Lin & Zabrucky, 1998). For example, the tendency of students across backgrounds and performance abilities toward *overconfidence*, or positively biased self-perceptions of abilities, was identified has been identified as a potential obstacle to learning: "overconfidence is a common phenomenon among young adult students that may result in inadequate learning due to premature termination of cognitive processing." (Lin & Zabrucky, p. 384)

In contrast, Bandura (1997) suggests slight overconfidence in one's abilities can be psychologically adaptive because overconfidence can have positive benefits on effort and persistence. In this view, poor calibration in the form of overconfidence can be reframed as a set of optimistic self-evaluations that may ultimately support taking-on challenges. Nonetheless, Bandura and other calibration researchers (e.g., Pajares & Kranzler, 1995) caution against grossly inflated overconfidence, suggesting that unrealistic overconfidence can lead students to engage in self-handicapping academic behaviors (Urdan, 2004) such as reduced studying and increased procrastination.

Since personal, social and cultural conditions are seen as important co-determinants of academic confidence, motivation, and behaviors, social cognitive theorists do not subscribe to global models of self-efficacy and performance (Bandura, 1997). Thus, it was important to develop a hypothesized model of self-efficacy, calibration, and performance which was based on the specific learning context at the research site.

Hypothesized Model and Research Questions

The hypothesized model for exam performance in advanced mathematics, shown in Figure 1, was based on an extensive review of related literature and was similar to models employed by Chen (2003) and Pajares and Kranzler (1995) in studies of mathematics self-efficacy among general student populations. The hypothesized model is a compact way of representing four quantitative research questions (Q1-Q4 below), which were addressed using structural equation modeling.

Q1 Does high school mathematics achievement have a significant effect on the amount of mathematics in participants' college major?

Q2 Do high school mathematics achievement and the amount of mathematics in participants' college major have significant effects on participants' calibration?

Q3 Do high school mathematics achievement, the amount of mathematics in participants' college major, and calibration have significant effects on participants' self-efficacy?

Q4 Do high school mathematics achievement, the amount of mathematics in participants' college major, calibration, and self-efficacy have significant effects on participants' performance on exams in advanced mathematics?

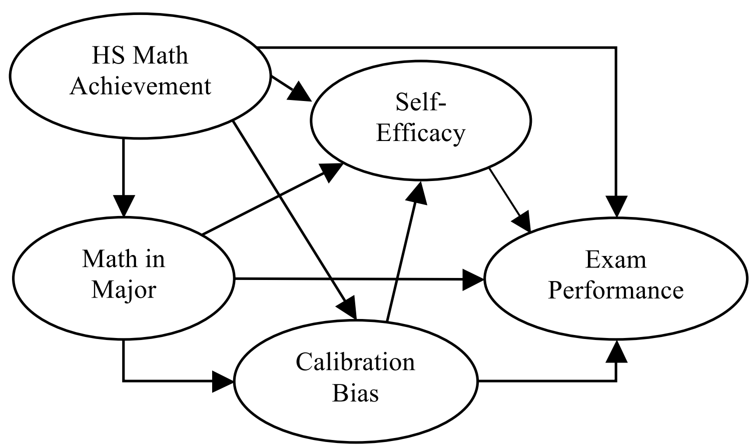

Figure 1. Hypothesized structural model for exam performance in advanced mathematics.

Methods

This study reports on findings from the quantitative portion of a mixed methods study which used a concurrent triangulation strategy (Creswell, 2003). Quantitative data sources included university enrollment data, background and self-efficacy survey responses, and copies of students' work on exams. Qualitative data sources included transcripts and artifacts from task-based interviews with 10 secondary teaching majors (see Champion, 2010).

Data Collection

Sample

There were 309 students enrolled in the 12 participating sections of advanced mathematics courses (M = 25.8, SD = 6.9) at the research site. Of the enrolled students, 17 (6%) did not take a final exam and 40 (17%) were enrolled in two or more of the classes, yielding a potential sample of 252 unique students who finished the classes. Of these, 210 (83%) consented to participate and complete data were available for N=195 students. Participating sections included three sections of Calculus I, two sections each of Calculus II, Calculus III, Discrete Math, and one section each of Linear Algebra, Abstract Algebra II, and Probability Theory. About half (49%) of the data comes from students' performance in Calculus I or II. When a student was enrolled in more than one participating section, only the data from the highest-numbered class was used for analysis.

Participants

Study participants ranged in age from 18 to 49 (M = 21.2, SD = 4.2). Most of the students (81%) were 18-22 years old, some of the students (11%) were 23-25 years old, or over 25 years old (7%). The percentages of study participants classified as Freshman, Sophomore, Junior, and Senior were 28%, 28%, 25%, and 18%, respectively. Study participants were almost exactly equally-distributed by gender (97 female, 98 male); the proportion of female students (50%) is substantially higher than national averages in advanced mathematics (Lutzer et al., 2007) but less than the overall proportion (60%) of female undergraduate students at the research site. Typical of the university, most of the participants self-identified as Caucasian (83%), followed in prevalence by Asian American (5%), Hispanic American (5%), and Other (7%). Though the study potentially included all students taking advanced mathematics at the research site, approximately half (49%) of study participants declared their primary major in mathematics or mathematics education. In particular, 12% indicated a major in Elementary Education – Mathematics Concentration and 37% indicated a major in Mathematics. About 79% (34/43) of the female mathematics majors chose the secondary teaching concentration, while just 37% (19/30) of the male mathematics majors chose the secondary teaching concentration. Other common student majors included Chemistry (10%), Earth Sciences (7%), Physics (6%), Biology (5%), Pre-Program (e.g., pre-medicine, pre-dentistry) (5%), and Undeclared (5%).

Data Analysis

The first four research questions (Q1- Q4) addressed effects posited by the structural path model of performance in advanced mathematics. Structural modeling was conducted using *R*, the open source implementation of S-Plus, and relied heavily upon structural model fitting routines in the package *sem* (Fox, 2009). The structural modeling procedures applied a strict interpretation of the underlying model, focusing on analysis of the correlation matrix and statistical evidence for inclusion or removal of the hypothesized directional effects of indicators and constructs (Suhr, 2008). Data collection instruments included a background survey, self-efficacy surveys in which students rated their confidence in being able to correctly complete exam tasks in the few minutes just before the actual exam, and graded copies of students' work on regularly administered final exams. Computation of self-efficacy and directional calibration scales followed procedures from several recent mathematics self-efficacy studies (e.g., Chen, 2003; Pajares & Miller, 1994).

Results

Descriptive Findings

Table 1 includes descriptive statistics of the indicator variables for the latent constructs High School Math, Math in Major, Self-Efficacy, and Calibration Bias. By definition, the means of the indicators for self-efficacy and calibration bias are ascending by “level.” For example, a student’s SE Level 1 rating indicates belief in being able to complete the mathematical tasks in which his or her classmates expressed the lowest collective rating. The means of self-efficacy indicators ranged from $M = 2.9$ to $M = 4.5$ on a scale of 0 to 5. The means of calibration indicators ranged from -0.4 for Level 1 (underconfidence) to 1.9 for Level 7 (overconfidence). Calibration means were significantly positive in 5 of 7 indicators at the $\alpha = .01$ criterion, suggesting general tendencies toward overconfidence in the calibration indicators.

Table 1.

Descriptive Summary of Indicators for High School Math Achievement, Math in Major, Self-Efficacy, and Calibration Bias

Construct	Indicator[a]	*n*	*M*	*SD*	Scale
HS Math Achievement	ACT Math	132	24.9	3.9	14 to 36
	HS GPA	133	3.4	0.6	0 to 4
	HS Self	195	4.6	1.1	0 to 7
Math in Major	Required Math	177[b]	23.0	15.2	3 to 45
Self-Efficacy	SE Level 1	195	2.9	1.3	0 to 5
	SE Level 2		3.2	1.2	
	SE Level 3		3.5	1.1	
	SE Level 4		3.7	1.1	
	SE Level 5		4.0	1.0	
	SE Level 6		4.2	1.0	
	SE Level 7		4.5	0.9	
Calibration Bias	Bias Level 1	195	-0.4	1.8	-5 to 5
	Bias Level 2		0.2	2.2	
	Bias Level 3		0.4	2.2	
	Bias Level 4		0.9	2.3	
	Bias Level 5		1.2	2.4	
	Bias Level 6		1.5	2.4	
	Bias Level 7		1.9	2.4	

Note. [a]“Level” indicator were formed by ascending within-class means. [b]Missing values for Required Math correspond to ambiguous majors (e.g., “undeclared”, “pre-program”). SE = self-efficacy rating, HS GPA = high school grade point average (capped at 4.0); HS Self = self-assessment of high school mathematics performance, Required Math = number of semester mathematics credits required by declared college major.

Table 2.

Distributions of Indicators for Final Exam Performance

Construct	Indicator	% Incorrect	% Correct
Final Exam Performance	Perf. Level 1	75	25

Perf. Level 2	63	37
Perf. Level 3	56	44
Perf. Level 4	42	58
Perf. Level 5	33	67
Perf. Level 6	27	73
Perf. Level 7	17	83

Note. Table entries indicate the proportion of students (N = 195) who correctly solved the corresponding final exam items. Items were randomly sampled from seven-level quantile groups based on item difficulty.

Indicators of final exam performance were based on dichotomous (correct-incorrect) scoring of seven final exam items by within-class means. As shown in Table 2, Performance Level 1, for example, represents students' performance on a difficult final exam item in their class – only about one in four students (25%) correctly solved the task corresponding to this first indicator. In contrast, 83% of participants correctly solved the final exam item corresponding to the Performance Level 7 indicator. Three indicators come from final exam tasks which were correctly solved by fewer than half of students; the remaining four indicators include greater than 50% correct responses.

The data suggested study participants experienced relatively strong performance in high school mathematics. The average ACT Math score of participants was M = 24.9, which corresponds to the 79th percentile of U.S. college-bound students (ACT, 2007) and is about one standard deviation above the university average (M = 21.6, SD = 3.7, t(1,236) = 11.3, d = .9, p < .001). In response to "Which of the following best describes how well you did in your high school math courses?", most students (87%) chose one of the descriptors OK, Good, or Very Good. The percentage (17%) of participants' GPAs at 4.0 or greater was larger than the average percentage (7%) of 4.0s at the university.

The measure of required semester mathematics credits in participants' primary college majors (Required Math) was calculated based on the distributions of students' majors. Since all mathematics majors were required to complete 40 college credits in mathematics, the large proportion of Mathematics majors in the sample produced a large departure from normality. The non-normal distribution, coupled with a lack of correlation between Required Math and the other study variables, led to its removal from the modeling estimation procedure.

Structural Equation Modeling Results

Model Estimation

After removing Required Math from the structural model specification, the *sem* estimation procedure for hypothesis-based model converged in 210 iterations. All directional effects in the model were significant at the α = .05 criterion with the exception of the posited direct effect of the latent variable High School Math Achievement on the latent variable Final Exam Performance (β = -.19, p = .40). Model fit indices included an overall chi-square of χ^2 (246) = 608.0, CFI = .70, NNFI = .67, SRMR = .08, and RMSEA = .09. The comparative fit indices (CFI and NNFI) were both below the .9 threshold for good fit, and the SRMR and RMSEA indices suggested marginal model fit. A likelihood-ratio test confirmed the structural model provided a significantly better fit than the measurement model ($\Delta\chi^2$ (6) = 146.7, p < .001).

Model FindingsFigure 2 shows the final structural equation model with the estimated standardized directional effects; the estimates of measurement errors are omitted from the diagram for readability. Standardized parameter estimates for the structural model were all significant at the α = .05 criterion, and values ranged from β = .21 (the loading of Bias Level 1 on Calibration Bias) to β = .78 (the loading of HS Self on HS Math Achievement). Effects *between* latent constructs (represented as ovals in the diagram) can be interpreted as estimates of the sign and relative magnitude of effects in the hypothesized model. For example, the review of literature supported direct effects of calibration bias on both final exam performance and self-efficacy, and the estimated coefficients suggested the negative effect of calibration bias (β = -.75) on final exam performance was comparatively larger than the positive effect of calibration bias on self-efficacy (β = .39).

As shown in Table 3, the large direct negative effect of calibration bias on final exam performance was mediated somewhat by an indirect positive effect of bias on self-efficacy. Similarly, high school math achievement had indirect effects on final exam performance through the separate effects of high school mathematics achievement on self-efficacy and calibration bias. The largest total effect on final exam performance was that of self-efficacy.

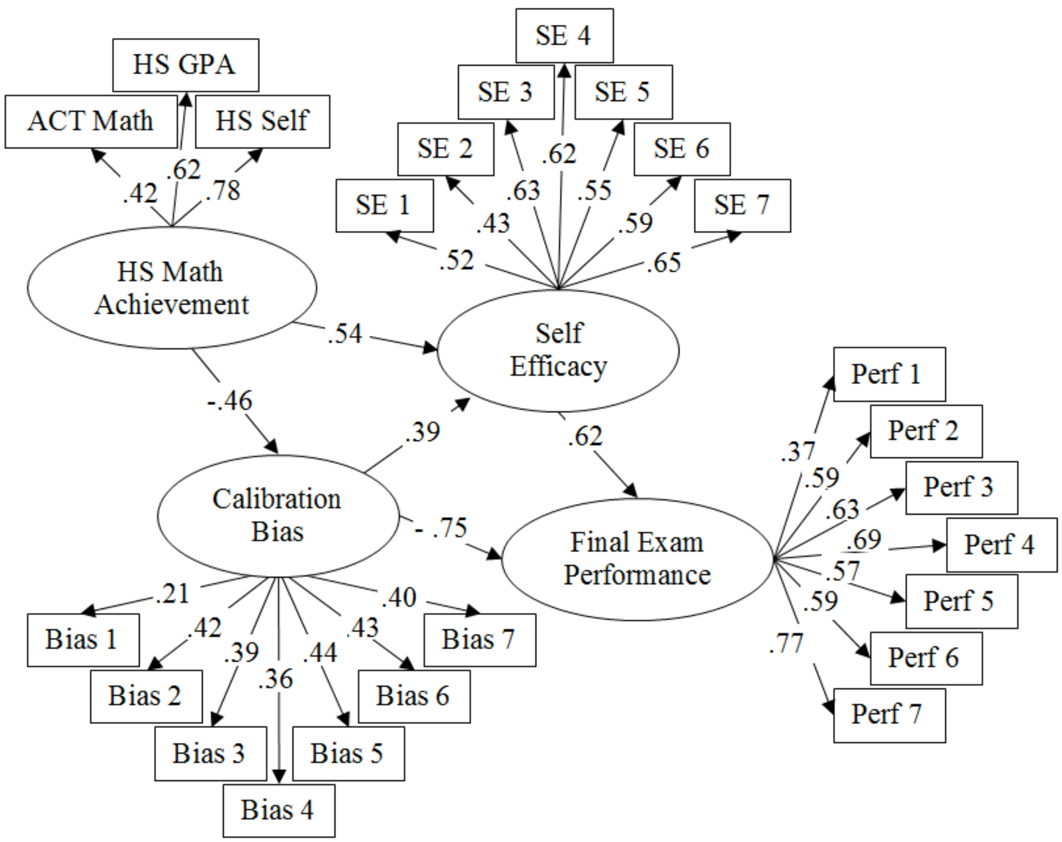

Figure 2. Standardized coefficients of directional effects in the final estimated structural equation model.

Table 3.
Standardized Direct, Indirect, and Total Effects between Latent Constructs

Effect of…	on…	Direct	Indirect	Total
HS Math Achievement				
	Calibration Bias	-.46**		-.46
	Self-Efficacy	.54**	-.18	.36
	Final Exam Performance		.57	.57

Calibration Bias				
	Self-Efficacy	.39*		.39
	Final Exam Performance	-.75**	.24	-.51
Self-Efficacy				
	Final Exam Performance	.62**		.62

Note. $^{*}p < .05$, $^{**}p < .01$.

Discussion

This study adds to existing literature on mathematics self-efficacy and calibration in mathematics. In particular, the study extends path analysis studies of calibration among middle school (Chen, 2003) and high school students (e.g., Pajares & Kranzler, 1995) to the important population of college students. The incorporation of structural equation modeling, with its affordances for multiple measures of underlying factors, also addresses implicit assumption in the prior path analysis studies that attitudinal variables can be perfectly measured by a single scale. The study findings suggest self-efficacy and calibration exhibit approximately equal and opposite effects on mathematics performance, providing support for Chen's (2003) findings that calibration has a weak effect on self-efficacy and that both self-efficacy and calibration have moderate to strong effects on mathematics performance. The similarities between estimates of directional effects in this and Chen, Pajares, and others' studies, taken in context of differing settings and measures of mathematics performance, suggest robustness for findings that self-efficacy and calibration have independent mediating effects within the long-understood influence of prior achievement on future performance in mathematics. Future research goals include (1) developing techniques for improving the calibration of students in advanced mathematics courses, (2) identifying potential differences in self-efficacy between teaching and non-teaching mathematics majors, and (3) documenting self-efficacy trajectories of secondary mathematics majors.

EMPOWERING PARENTS THROUGH KNOWLEDGE OF HOW CHILDREN LEARN MATHEMATICS

David Pratt
Purdue University North Central
dpratt@pnc.edu

David Felkes
Purdue University North Central

Heidi Stevenson
University of the Pacific

Parents want to help their children succeed in school, especially in mathematics however; they are often inadequately prepared to do so. The primary hypothesis of our research is that children's understanding of mathematics can be improved by empowering parents with resources focused on how children learn mathematics. Emergent themes that evolved as the result of these beginning research efforts are: 1) Parents desire and need more mathematical content knowledge 2) Parents think differently about how to help their child as a result of learning about children's thinking about math 3) Parents are frustrated by their child's struggle with mathematics.

Children are not the only ones doing homework these days. As more and more schoolwork is sent home at earlier and earlier ages, parents also feel the pressure to help their students succeed (Kohn, 2006). Many parents, however, are ill-prepared to work with children, especially in mathematics. Therefore, it is not surprising that parents expressed a desire to be more effective in helping their children with schoolwork (Mapp, 2003).

Despite altruistic intentions, most parents do not have a grasp of cognitive development or basic knowledge of how their children think about mathematics. Without ill-intent, they often rely on ineffective questioning, explaining and examples when working with children (Eloff, Maree, & Miller, 2006). Unfortunately, well-meaning parents generally do not know the importance conceptual understanding plays in assisting their child in becoming a life-long learner of mathematics.

It is not that all parents and primary caregivers have been unsuccessful in learning mathematics themselves, but more often than not those who have been successful have learned mathematics as rules and procedures. They might be able to tell children the rules but unless they understand the concepts behind the rules; they will not be effective in helping children understand mathematics. By knowing how children think mathematically, parents can make appropriate interventions that provide powerful learning opportunities.

Our initial research with parents (Feikes, Swchwingendorf & Stevenson, 2010) offered four emergent themes, three of which will be the focus for this paper. The purpose of this study is to explore how previously published materials on Connecting Mathematics for Elementary Teachers (CMET), can be adapted for use with parents to increase their knowledge of children's thinking about mathematics and efficacy to assist their children. Ultimately, the goal is to positively impact student learning of mathematics.

Review of Literature

The Connecting Mathematics for Elementary Teachers, (CMET), an NSF supported project (DUE 0126882 and DUE 0341217) funded the development of the commercially published textbook CMET (Feikes, Schwingendorf, & Gregg, 2009) and supplemental materials for prospective elementary teachers and their instructors (http://www.cmetonline.com). Literature on mathematical content knowledge (e.g. Hill & Ball, 2004) and the importance of understanding children's thinking (Empson & Junk, 2004; Steinberg et. al, 2004), contributed to the creation of these materials.

Results from CMET indicated that preservice teachers who used the CMET materials increased their self-efficacy (Pratt, Feikes, & Hough, 2007, 2007) developed beliefs that were more aligned with conceptual understanding of mathematics (Hough, Feikes, & Pratt, 2006), and developed greater pedagogical content knowledge—the mathematical knowledge necessary for teaching (Feikes, Pratt, & Hough, 2006).

There are currently two other nationally funded projects focus on parents and mathematics education. Math and Parent Partnerships, (MAPPS), attempts to engage parents in mathematics with their children. The intent is that parents would be to support their children's mathematical learning. After participating in the MAPPS project students had better attitudes about mathematics and liked math more. They also indicated that they were more likely to try harder after participating in this project with their parents (MAPPS, 2007). Another project, *The Role of Gender in Language Used by Children and Parents Working on Mathematical Tasks* at the University of Hawaii, focuses on gender-related differences in language and actions used by children and parents when working on mathematical tasks.

Methodology

Due to the limited literature on parents' work with children on mathematics outside the classroom and the exploratory nature of this study, a variety of data collection techniques were used to gather information from a wide range of participants. To develop an understanding of the effectiveness of the CMET materials to assist parents in helping their children with learning mathematics and to identify revisions that are needed to meet the needs of parents and their children, it was deemed appropriate to focus on a limited number of parents who could be easily accessed and were identified as wanting to assist their children with homework. It is left to later studies to contrast the behavior of these parents with others who are not as readily interested in assisting their children with mathematics homework.

Data Collection

The primary methodology is a design experiment (Brown, 1992, Collins, 1992; Cobb, Confrey, diSessa, Lehrer & Schauble, 2003). This methodology has been modified to fit with the research conducted in this study. Features of the research that lend itself to a design study are the application of innovative instructional material, the testing of theories of how to help parents help children, and the cyclical nature of design.

A design experiment provides the tools to test theories of how parents work with their children on mathematics and how to improve these interactions. Theories on parent learning are 'humble' theories in that they target domain-specific learning processes (Cobb, et. al, 2003).

Further, this study entails five key features described by Cobb et al., (2003) it: 1) develops theories, specifically theories parent learning and parent enablement, 2) is interventionist—new activities will be employed, 3) tests these theories and materials with parents in real learning situations, 4) is iterative in that both materials and theories will be revised in a cyclical process, and 5) is pragmatic—the materials will be realized with real parents working with children.

The present study's varies in two ways from Cobb et. al. This study focuses on parents interacting with their children as they help them with mathematics outside of the classroom. A second key difference is that we have collected anecdotal evidence and interview data about the learning process without actually observing and intervening in the parent/child episodes. Despite these differences we consider the design experiment as the best fit to our research purposes.

Data Sources

Data for this study consisted of a) written reviews of the materials, b) course work in a graduate mathematics education course, c) transcripts from parent focus groups, and d) transcripts from parent interviews. For clarity, these are all independent data sources and there was no overlap of participants. The purpose of collecting these data was to examine how parents might use knowledge of how children learn mathematics in helping children learn mathematics.

Written Reviews of CMET Materials

There were two groups of parent participants who provided written reviews of using CMET with their children, one of which was a group of graduate students. Two parents were asked to review the CMET materials in regards to its possible contribution in helping them with their children. They completed a questionnaire in which they were asked to assess each chapter, what they learned, and how they used any of this information with their children. These participants were paid a small stipend. Several graduate students who were also parents reviewed the CMET materials as part of a mathematics education graduate course for elementary teachers. They were asked to evaluate the CMET materials in regards to the degree to which it contributed to their ability to assist their children with mathematics homework.

Focus Group Interviews

Two focus groups were conducted with parents at local elementary schools, one school had a high rate of free and reduced lunches (83%) and the second was in a middle class community and was Four Star School. The focus group sessions were one hour in length, audio-recorded and transcribed. This corpus of data will be used to determine how knowledge of children's mathematical thinking might be used by parents working with children, how parents interpret the resources, and more importantly how they use CMET resources working with children.

Individual Interviews

Two parents whose children were having difficulty in mathematics were presented with selected sections of CMET that related to the difficulties that their children were having. These parents were interviewed and the interviews transcribed. The questions were brief, asking them what did they learn by reading the resource materials and how did they use them with their child.

Data Analysis

The data sources listed above were submitted to Constant Comparative Analysis to produce emergent themes (Glaser and Strauss, 1967). These themes were substantiated, modified, or rejected through review by two researchers. Every effort was made to triangulate the themes with multiple data sources (see Results section).

Results

The overall goal was to discern if the CMET materials adapted for parents on how children learn mathematics are useful, how these types of resources might be used by parents, if using these resources impact children's learning of mathematics and how they can be improved. The results presented here are only include the initial emergent themes.

1. Parents see the need to learn mathematics to help their children.

One theme that emerged was that parents want to know more mathematics in order to help their children. A parent in the focus group was talking about her son's homework that night. "My son understands it much better than I do, but in order for me to help him, I have to understand it." She realized that she could not help her son on his homework unless she understood the mathematics. Later in the focus group she indicated that she could use the Internet to help her learn more mathematics, but she currently does not have the Internet. She wants to help her son and is even aware of resources but does not have the resources at her disposal.

Parents from both the focus groups had difficulty understanding lattice multiplication and partial products. In regards to lattice a parent said, "I was like man, how did they get this number? Because it didn't add up right at first. Then you have to start going an angle with it, and I thought okay, I got it now." Again, the parent may attribute his not understanding lattice multiplication to his lack of understanding of mathematics.

2. After using the adapted CMET materials, parents began using a different approach to help their children.

One parent who reviewed CMET indicated that using these materials changed how she approached working with her daughter. She found herself more willing to let her daughter experience mathematics rather than just telling her how to do it. This was most evident with problem solving activities where she found herself "restraining myself to not 'jump in' and allow her to experience problem solving for herself." She began to realize that her way of helping her daughter may not be the best approach. In a broader sense she took a more reform-oriented view to teaching. She moved from 'teaching as telling' and acted in a way that supports the notion that children must construct their own knowledge of mathematics.

The following self-reported example from a parent who reviewed CMET illustrates evidence of both learning and change in how this parent interacted with her son.

> My son Nathan had 'created' his own way to multiply two, 2-digit numbers. 23 x 45 = (20 x 40) + (3x40) + (3x5) + (20x5). I kept trying to convince him that the traditional algorithm was more efficient because his method became cumbersome for 3-digit numbers - I then found out his method was called partial sums and some children are taught this way to multiply.

After reading the CMET materials, rather than fight her son, this parent saw his work as a precursor to the traditional multiplication algorithm. She explained, "So we used his partial sums as a jumping off point to get to the traditional algorithm - trying to look where his pieces matched with "mine" as he calls it.

Another parent, who reviewed CMET in the graduate course, began to engage her child in statistical activities described in the materials. At first she thought the chapter in the CMET on statistics and data analysis was for children in the upper grades. Reading examples about how young children can collect and represent data inspired her to encourage her child to do the same.

> I found myself actually having my 4-year-old collect data with a mini clipboard. I had him go around our house when we had company lately and see who was wearing jeans, pants, or skirts. He drew pictures and reported his "data" to us at dinnertime.

When asked if the CMET materials were helpful a parent responded, "Yes and no. It helped me to understand what she was struggling with, but she still struggles with [that]." For example, if her daughter solved 4 x 5 = 20 and then is asked 5 x 5, her daughter had difficulties solving the problem. The mother explained, "So when I ask her what 5 x 5 is, she doesn't understand that you add another 5. She isn't seeing it as four groups of five. I don't know how to help her." This parent seems to have internalized some information from the materials. She sees that multiplication facts are related and that she wants her daughter to understand that multiplication is repeated groups.

These three examples above illustrate that parents were reading the CMET materials, learning from them and, interacting differently with their children from what they had prior to reading the materials.

3. Some parents are frustrated helping their children with mathematics.

Another theme that emerged was the frustration of parents whose children were struggling with mathematics. A parent, of a third grader in the focus group, expressed his frustration when his daughter solved a problem like 6 + 2 on her homework and then later in her homework she did not know how to immediately solve: 2 + 6. "And then their fingers go up. And I'm like, why would you, you know, why would you have to do [that]. Shouldn't have to do that we've been doing that since Kindergarten."

Regarding this frustration the same parent said, "She gets confused and she gets frustrated and she usually just lets it go- don't even want to mess with it no more… then I get upset, and I may start getting a little loud."

Conclusions

Parents want to be a valuable resource to their children but they frequently lack the knowledge necessary to help with math homework (Eloff, Maree, & Miller, 2006). One way to support parents is to provide resources to discover how their children actually learn mathematics. With this knowledge, parents will be empowered to contribute to their children's mathematical development, hopefully resulting in student learning.

The findings of this exploratory provide an impetus to continue research on adapting CMET materials for parents and continue our search for funding. The fact that parents see the importance of learning about how children learn mathematics reinforces the need for CMET adapted materials. The finding that parents are actually using the information to work with their students with a greater understanding of student thinking, seems to make the creation of materials for parents a necessity.

From the third emergent theme, it appears that not only must these materials be provided in an understandable format to parents, and suggestions should be given on how to use this knowledge; but that parents' ways of thinking about how their children learn must also be addressed to alleviate frustrations. Perhaps, addressing the beliefs and values of parents is beyond the scope of our intended resources, but it is an area of that must be considered.

Another significant question, which we have not addressed is, "Does parents' use of CMET resources help children gain a deeper mathematical understanding that results in measurable student learning?” This question is difficult to address outside of the school setting but is the ultimate aim of this and other intervention efforts to improve mathematics education.

With more homework and need for parents to help with mathematics, it seems necessary to provide assistance to not only students but also to parents and caregivers. Knowing that parents’ involvement with their children’s schoolwork improves students’ performance and their attitudes about math, parent assistance about how children learn mathematics become paramount. The adaption of CMET materials for parents appears to be a rich source of information to increase parent’s ability to improve their child’s learning of mathematics and further research is warranted.

IDENTITY AND POWER ISSUES IN MATHEMATICS FOR ADOLESCENT FEMALES

Lynda R. Wiest
University of Nevada, Reno
wiest@unr.edu

Stephanie Vega
University of Nevada, Reno
stephanie@unr.edu

This paper presents the results of a study involving surveys and interviews conducted with 76 Northern Nevada Girls. We investigated how the girls perceived themselves and others in relation to mathematics, what factors influenced those perceptions, and how those perceptions influenced the girls in mathematics. Findings are organized into three main themes: identification with mathematics, outside influences on mathematics identity, and power relations

Females continue to be underrepresented in the mathematical sciences, and they perform more poorly in and have less positive dispositions toward mathematics than males (Wiest, 2011). Because females' dispositions toward mathematics tend to develop relationally within social contexts (Zeldin et al., 2008), issues of identity and power may be important to examine in efforts to support and encourage females in mathematics. Although identity has not occupied a central position in mathematics education research and thus lacks a common, accepted definition (Cobb, Gresalfi, & Hodge, 2009), the construct is emerging as a topic of interest in gender and science-oriented fields (Brotman & Moore, 2008). The purpose of this research was to investigate issues of power and identity in relation to mathematics for a group of adolescent girls. We investigated how the girls perceived themselves and others in relation to mathematics, what factors influenced those perceptions, and how those perceptions influenced the girls in mathematics.

Related Literature

The General Construct of Mathematics Identity and Its Impact

Wigfield and Wagner (2005) describe identity in general as "an overall sense of who one is" (p. 228). Personal identity encompasses perspectives individuals construct about the world around them and themselves in relation to that world, for example, how others perceive them and what role they occupy within a community (Hodge, 2006; McCarthey & Moje, 2002). It is a value-laden construct in which individuals determine the degree to which they adopt or resist others' expectations (Cobb et al., 2009).

Although personal identity tends to be stable at any moment (Esmonde, 2009), it is a dynamic construct that evolves over time (Gaganakis, 2006; Hodge, 2006; Owens, 2007/2008; Solomon, 2007). Identity can vary in different contexts, situations, and relationships and is thus complex and domain-specific (Esmonde, 2009; Gaganakis, 2006; Hodge, 2006; Leatham & Hill, 2010; McCarthey & Moje, 2002; Wigfield & Wagner, 2005). Therefore, student identities must be examined within the context of a specific subject area. Martin (2009) describes mathematics identity as

> the dispositions and deeply held beliefs that individuals develop about their ability to participate and perform effectively in mathematical contexts and to use mathematics to change the conditions of their lives. A mathematics identity encompasses a person's self-understanding and how others see him or her in the context of doing mathematics. (pp. 136-137)

Mathematics Identity Formation

Identity is a negotiated construct that is influenced by a number of social, cultural, cognitive, and affective factors (Gaganakis, 2006; Martin, 2009; Owens, 2007/2008). Because identities are located within relationships (e.g., McCarthey & Moje, 2002), peers, teachers, school counselors, families, the community, and others influence identity formation (Axelsson, 2009; Esmonde, 2009; Gaganakis, 2006; Hodge, 2006; Martin, 2009; Mireles-Rios & Romo, 2010; West-Olantunji et al., 2010). For example, the way in which an individual is positioned within particular social and academic settings influences personal identity in those situations (Owens, 2007/2008; Solomon, 2007). Nevertheless, individuals exercise varying degrees of agency in determining how to process and respond to external assessments of themselves (Hodge, 2006). Peers have a particularly strong influence on young people's development, perspectives, and behaviors, such as their self-confidence and academic achievement motivation (Bissell-Havran & Loken, 2009; Hoogeveen, van Hell, & Verhoeven, 2009; Keck, 2008; Wigfield & Wagner, 2005).

Another factor that can influence mathematics identity is past and present mathematics performance, such as grades and test scores (Axelsson, 2009; Keck, 2008). One's sense of academic competence and affective characteristics such as confidence, motivation, and anxiety influence identity formation and stem from such factors as possession of academic knowhow and social support (Axelsson, 2009; Owens, 2007/2008; Wigfield & Wagner, 2005). Students' self-concept, including competency-related beliefs, has been shown to decline from early adolescence through secondary school (Nagy, Watt, & Eccles, 2010; Wigfield & Wagner, 2005).

Teachers' beliefs and classroom practices, such as those that foster or inhibit competence and motivation or promote peer comparisons, can shape mathematics identities (Martin, 2009; Wigfield & Wagner, 2005). Selected other instructional practices that can influence identity development are use of group work, which can proceed equitably or inequitably, ability grouping, and technological learning supports (Esmonde, 2009; Owens, 2007/2008; Solomon, 2007). Research shows that students develop more positive identities, including a stronger sense of agency, in classrooms that emphasize student thinking, responsibility, and active, collaborative participation versus authoritative, teacher-centered classrooms where students mainly follow directions and perform prescribed procedures (Cobb et al., 2009; Keck, 2008; Solomon, 2007).

Students' social identities, such as gender, race/ethnicity, national origin, and social class, are important factors in identity formation (Brotman & Moore, 2008; Gaganakis, 2006; Solomon, 2007; Wigfield & Wagner, 2005).

Identity and Power in Mathematics

Identities are constructed within social settings in which individuals are positioned in ways that give them differential status and power (Esmonde, 2009; McCarthey & Moje, 2002; Solomon, 2007). Hodge (2006) describes power relations as "situations in which ideas and practices of particular groups or individuals are valued over those of others" (p. 377), which can include ways of reasoning, communicating, and demonstrating knowledge. Like identity, power relations can change over time as interpersonal dynamics shift based on various influential factors from within or outside the group (e.g., Martin, 2009).

Research Purpose and Method

The purpose of this research was to investigate issues of power and identity in relation to mathematics for a group of adolescent girls. We investigated the following questions: How do adolescent girls perceive themselves and others in relation to mathematics? What factors influence these perceptions? How do these perceptions influence the girls in mathematics?

Participants in this study were 76 Northern Nevada girls who voluntarily attended a six-day, residential summer mathematics and technology camp during the summer of 2009 or 2010 (36 and 40 girls, respectively). They entered grade seven (50 girls) or grade eight (26 girls) the following fall. Of the 74 girls who disclosed their race/ethnicity, 50 were White/non-Hispanic, 13 were Hispanic, 8 were Asian/Pacific Islander, and 3 were a mix of two or more categories. About one-third of the girls participated in the program on a financial-need scholarship as determined by eligibility for free or reduced-cost lunch. Research participants completed a written five-item survey upon entering the summer girls' mathematics and technology camp. The open-ended questions included questions related to how the girls viewed themselves as "mathematicians," who influences those views, and what perceptions the girls held of others in mathematics. Four girls also participated in individual interviews at three points in time: the camp beginning, the camp end, and four months later when they were back in school. The girls were asked questions related to how they perceive and want to perceive themselves in relation to mathematics, what factors influence these perceptions, and potential future career aspirations in a mathematics-related field. We analyzed our survey and interview data by reviewing it carefully for themes related to our research. We sorted the data into three *a priori* themes that appeared in the professional literature on identity and power: identification with mathematics, outside influences on mathematics identity, and power relations.

Results

Identification with Mathematics

Ability. In reference to how "good" they are in mathematics, respondents described positive and negative associations related to their mathematics abilities or capabilities. Many indicated positive associations with mathematics by describing that they see themselves as "mathematicians." Participants used such terms as "kinda good," "smart," and "advanced" to describe themselves in mathematics. Several positioned themselves as average or in the "middle" in terms of mathematics ability. Participants who reported negative associations with mathematics expressed difficulties with learning mathematics or described mathematics as an area of needed academic improvement.

Performance. Some participants based their perspectives toward mathematics on performance in general or performance on specific topics and skills. During Interview 1, a respondent said, "I do think that I'm good at math, but sometimes I don't like if I don't get a problem." This participant later stated in Interview 2 that she felt less confident about herself during the camp in reference to "two hard math [word] problems in the mornings." Another interviewee reported in her first interview that she is good at mathematics because of her multiplication and integer computation skills. However, she did not believe she was good at long division. Other mathematics topics that participants commented on in describing themselves in relation to mathematics based on performance included speed in solving a problem, understanding a concept or recalling a mathematics fact, and frequency of errors or mistakes made when doing mathematics.

Dispositions. Over one-half described themselves as having a desire to learn mathematics and being serious about mathematics. They said they like mathematics and enjoy facing challenging problems. A few other respondents described disinterest in or apathy toward mathematics, often due to their struggles with the subject matter.

A common belief among participants was that “everyone has potential,” in other words, that personal agency plays a role in mathematics ability/performance. One-fourth of the survey respondents wrote that those who are good at mathematics typically demonstrate determination to do well in mathematics. They explained that people must “try” in class, pay attention during lessons, ask questions when they need help, and study. Whereas 16 of 47 girls of higher-SES expressed the belief that personal agency thus plays a role in mathematics, only 3 of 24 girls of low SES did so. Conversely, three participants claimed that some people are naturally better at mathematics than others. One stated that being better at mathematics is a “gift from god.”.

Almost all participants described the usefulness of mathematics in everyday life. Most participants also said mathematics was very important to their future career. Five participants, however, were more equivocal about their valuing and perceived usefulness of mathematics. For example, three weren’t sure how important it would be for their career (e.g., singer or author).

Participation. Some participants described their willingness and effort to actively participate in mathematics class at school. They reported exerting effort to learn new concepts and skills, such as paying attention in class, taking notes, doing homework, and studying for tests. Ten participants described providing mathematics help to peers, mainly friends, during mathematics class and at lunch or after school. Five expressed a lack of interest in pursuing additional mathematics participation by stating that they only did required assignments and activities to achieve a good grade in mathematics class. One participant explained that she was not doing well in mathematics, so she came to the summer camp to try to improve her skills. In reference to the math and technology camp participants had just entered while completing the surveys for this research, only 3 girls reported that they had ever attended a similar, supplementary, out-of-school time program in a mathematics-related field.

Outside Influences on Mathematics Identity

Family members, including parents, grandparents, aunts, uncles, and siblings were reported as influences on mathematics identity. Family members provided support, assistance, feedback, and encouragement. Participants said parents and siblings helped them with homework. Students also described parents’ attitudes towards mathematics as influences. One student wrote: “My parents are very supportive of my math skills. They always joke that they don’t know where it came from. My mom says it’s a gift that she can even add and subtract!” One-third of the girls described their parents’ love for mathematics as a means of support and encouragement.

Teachers were also identified as influences within the instructional environment. For positive influences, several participants described how their teachers expressed or modeled their enjoyment of mathematics or made it fun, and one wrote, “My teacher calls me a math wizard.” In contrast, teachers also exerted negative influence on participants’ mathematics identity. Three students described feeling “put down” by mathematics teachers, and one interviewee noted, “My last math teacher caused me to think a little less of my ability in math.”

About one-third of the participants described the level of support provided by teachers as influences on mathematics identity. Most reported that they received enough mathematics help from teachers. One participant explained that her teacher would slow down and work out the problem with her. Several students reported that they did not receive an adequate amount of help. Only 4 of the 24 low-SES participants compared with about half of higher-SES participants reported teachers as an influence in how they see themselves in mathematics. The role of the teacher and type of instruction is evident in this quote from a rising seventh grader:

> Math camp helped me a lot because we got to use pictures and stuff. At my school, they use pictures too, but they just do answers. My math teacher, I didn't really get to know math or do math or anything, because he tells us the answers…and he won't even let us work out the problem or anything…. So, I like being here because I get to know math and I get to work it out for like 10 minutes or so with a group and at my school, we had to work it out individually unless our desks were put into groups…. I was scared to come to math camp because I was scared that all of the other girls would know how to do the problems and I wouldn't because of my math teacher giving me all the answers.

Other influences indicated were peers and television/movies. About half of the respondents explained that friends and classmates supported or influenced their association with mathematics in various ways. Some respondents described friends and classmates passing negative judgment on their mathematics abilities. Students described peers calling them names, such as "nerds" or "brainiacs" for reasons such as enjoying mathematics, doing well in mathematics, and attending the math camp. Four participants mentioned television/movies as outside influences. Two participants commented on seeing characters on television shows with mathematics-related careers and who enjoy doing mathematics. Another participant wrote that movies have an impact on her because filmmakers cast people who are nerdy (seemingly a negative connotation).

Participating in "extra" math experiences is likely another influence on mathematics identity. All four girls who participated in interviews said at both follow-up interviews that the camp influenced how they perceived themselves in mathematics. They mostly discussed having gained new knowledge and skills, new methods for doing mathematics, and increased confidence as a result of these improvements and expansions.

Power Relations

One-fifth of the participants identified differences in positioning and opportunities within the classroom and society as a whole in relation to mathematics. These participants wrote that students are given different opportunities in class based on their level of understanding of mathematics. Three participants perceived a difference in the amount of respect given to certain types of students. One wrote, "Teachers take smarter kids more seriously and give them more respect than average or below average students." Another stated: "My 7th grade teacher wouldn't actually see me much because she would only be with the smart ones and leave the ones that really need help behind." In contrast, two of four interviewees who self-identified as Hispanic did not perceive differences in positioning within the math camp context. In response to what things at camp made her feel good about herself in mathematics, one stated: "I think that during math camp, I knew that the other girls around me were all on about the same page and that I didn't feel like I was too far ahead or too far behind." The other described fear about attending the math camp because she "was scared that all of the other girls would know how to do the problems…they would be mean to me or tease me." She explained that the setting turned out to differ from what she had anticipated. She found her peers helpful and supportive.

Within a societal context, six participants wrote survey comments indicating perceptions that certain groups or types of people have better ability or are treated differently than others in mathematics. One wrote, "Math is known as a hard subject with only men capable for succeeding," and another simply stated, "Men are respected more." Other girls addressed additional biological characteristics, including hair color (blond) and race/ethnicity, that they perceived to influence the treatment some people receive. In contrast, eight participants reported that everyone has similar mathematics ability.

Discussion and Closing

Most research participants expressed some type of opinion about themselves in relation to mathematics or vice versa. This indicates that most girls had some type of conscious opinion on this matter in one direction or another, which may indicate the salience of the mathematics-self relationship. Although most comments were positive, some were negative. The girls were also asked to comment on the value of mathematics and whether or not various groups of individuals are equally capable in mathematics. These perspectives also tended to be more positive than not. Of the majority positive responses to these questions, we suspect that some were rehearsed rhetoric the girls had been "fed" at some point from teachers, parents, or others. For example, the mathematics camp that all of these girls attended opened with a parent-camper session in which the first author (Wiest) emphasized that females and males have equal mathematics capabilities and that effort and experience are highly important factors. This occurred one to two hours before the girls completed the surveys prior to the main camp activities beginning. It is likely that this and similar experiences influenced some girls to state what they have heard and adopted, likely unexamined in many cases. Nevertheless, the girls did offer a number of examples of the utility of mathematics that did not arise in the camp's opening address. Again, it is uncertain whether these "tidy" examples were memorized from some source or were authentic. Similarly, a number of girls articulated the importance of mathematics to their future career by perceiving this importance in general or, especially, by naming a specific career. These may also be regurgitated comments heard from well-meaning adults.

We suspect that deeper probing would yield more fragile and less positive self-images in relation to mathematics and that the positive notions the girls repeated may not be fully integrated into some or many of these girls' self-perceptions. Mixed perspectives indicating confidence or lack thereof were evident across but also within girls. The variability demonstrated within girls, such as girls who described greater ability and confidence with some mathematics topics compared with others as well as awareness of societal perspectives compared with their own, can mean that these girls' have good self-awareness into their own strengths and weaknesses, which can be useful to guide future learning. However, it may also signify easily malleable and thus fragile self-conceptions in relation to mathematics that depend on mathematics topic, mathematics performance, and others' opinions, in other words, external factors beyond their control.

The role of personal agency in determining one's relationship with mathematics is important. A belief that one can strengthen one's positive connection to mathematics with appropriate experience and effort is important to help girls feel some sense of personal responsibility for and control over this relationship. A belief that predetermined or external factors alone shape this relationship, such as biology, the mathematics content itself, or others' perspectives, can lead to fatalistic notions that could cause some girls to "accept" their position in relation to mathematics and other individuals. In the present study, about one-fourth of the participants expressed the belief that personal agency plays a role in mathematics. However, one-third of higher-SES girls but only one-eighth of low-SES girls offered this perspective. This is an area for concern.

Higher-SES girls likely have more opportunity for furthering their academic skills through attendance at out-of-school-time programs, travel, and possession of educational materials at home. Perhaps their parents vocalize the importance of working hard and an expectation for success and may provide more role models in mathematics-oriented endeavors. Low-income students may have less access to opportunities due to financial constraints, which limit opportunities, resources, and time (e.g., Wiest, 2010). Further, they may be disenfranchised from school, finding it harder than higher-income students to believe they are taken seriously in school or that academics can play an important role in their future (see also Martin, 2009).

The opinion of others is important to girls. Peers clearly play an important role. However, adults also have an important impact on girls' self-perceptions, performance, and participation. This appears to be more complex than meets the eye. For example, one girl noted in a positive sense, "My parents are very supportive of my math skills. They always joke that they don't know where it came from. My mom says it's a gift that she can even add and subtract!" Whereas this comment appears to be positive on the surface (and is to some degree), the subtext is that the girl's mathematics ability came from some unknown place rather than being a result of the girls' own intelligence and effort. Further, it provides a weak female role model in the mother's comments about herself in relation to mathematics. This type of comment can plant deep seeds that are likely digested and may surface in the form of negative dispositions at some point. One interviewee clearly links her concern about her teacher only giving the students answers and not letting students figure them out for themselves to her lack of confidence doing mathematics because she believes she is not properly prepared with the needed skills.

Mathematics participation is affected by financial resources and opportunities for out-of-school-time (OST) experiences, as well as awareness and encouragement. The girls in this study had little opportunity or encouragement to pursue OST mathematics. The important role of the teacher is evident where one girl noted that she had not previously participated in programs similar to the mathematics camp because her teacher had not suggested it. Because greater participation in additional mathematics experiences appear to be linked to girls' dispositions (e.g., confidence) and self-assessed ability, it follows that greater mathematics participation can likely improve girls' mathematics identity. It is thus imperative to offer *all* girls more mathematics opportunities and to encourage and support their participation.

It is clear from this study and others that there is much room for hope in relation to girls' present and future relationship with mathematics. However, proactive work in this area is still needed. The fact that some girls, although small in number, perceive societal perspectives and power relations that academically and socially position people in particular ways that are not always positive and productive is another source of evidence that our work is not done.

DEVELOPING COMPETENCY AND MATHEMATICAL KNOWLEDGE USING PROBLEM SOLVING

Verónica Vargas Alejo University of Quintana Roo, México
vargasalejo@uqroo.mx

César Cristóbal Escalante
University of Quintana Roo, México
cescrist@uqroo.mx

This article reports on the type of mathematical competencies that students exhibit at the superior level of education to solve problems which involves concepts such as the unknown quantity, the variable, and the solution of a linear equation. The role of the professor is emphasized, as well as his/her interventions to help students develop comprehension. The discussion of competencies in which this paper is based is established by De Corte (2007). The problem reported forms part of a series of problems solved in an environment of Problem Solving. The results reflect the mathematical knowledge exhibited in the students' procedures.

Introduction

In this era of rapid advances both in science and in technology, there is a demand to have people who are not only more informed, but also better educated. We require an education that will form competent human beings able to make contributions for the further development of society. Various questions emerge upon this theme: What does it really mean to develop competence? How has mathematics formed part of this competence? What does it mean to develop mathematical competence? How should the learning process that we use for our students enhance their acquisition of mathematical skills? What is the role of the professor in the development of this competence?

This article will discuss questions such as: What mathematical competencies are exhibited at the superior educational level to solve problems that require linear equations? Another question is: What type of interventions can the professor use to help his students develop mathematical knowledge and competencies? Based on a final report given in by students in this study, it is possible to identify the procedures commonly used by students who solved Problem 1, here reported, in a Problem Solving environment (Schoenfeld, 1985). Thus it is possible to identify students' competencies and mathematical knowledge. The professor's role in helping students to develop their mathematical knowledge and skills will also be noted. The discussion about mathematical competence found in this paper is established in De Corte (2007).

Review of Literature

Obtaining mathematical competence implies acquiring mathematical disposition, of which is characterized by five aspects (De Corte, 2007, p. 20, 21): an accessible base of knowledge, well-organized and flexible, the use of heuristic methods and meta-knowledge, positive mathematics-related beliefs, and self regulatory skills. Furthermore, this competence implies that the student has the capacity to transfer these skills and knowledge to new tasks.

The acquisition of the mathematical competence according to De Corte (2007) requires an active-constructive, self-regulated, situated, and collaborative process of learning. An environment of collaboration, where it is permitted that the student establishes meaningful mathematical knowledge is important. One theoretical perspective in the teaching and learning of mathematics that considers and uses discussions such as the one hereby presented is Problem Solving (NCTM, 2000|2003; Schoenfeld, 1985; Santos, 1997).

This theory proposes that the teaching of mathematics should be approached as a problem-solving domain where students construct a deep understanding of mathematical ideas and processes by engaging them in doing mathematics (Schoenfeld, 1985; Santos, 1997). It implies discarding the idea of introducing the problems in the curriculum with the only purpose of memorizing a set of definitions, algorithms, and techniques to solve routine activities (Schoenfeld, 1985).

In Problem Solving theory, the role of the professor is fundamental and definitely influences the formation and creation of the classroom as a place of learning (Grouws, 2004) where resources, heuristics, control and beliefs are important. The professor can create favorable learning conditions in the classroom where the following points are taken into consideration: the development of a significant answer by the student himself /herself, student justification and explanation of answers, ability on the students' part to understand the meaning of explanations and justifications offered by other students. Classroom environment should be provided in which the students can feel confident to communicate their ideas, ask questions, use multiple representations, construct ideas, and formulate exceptions to the rule (Santos, 1997). On the other hand, the students who are in disagreement or those who do not understand something in the classroom feel sufficient self assurance to question and challenge their classmates. The social interaction that takes place in the classroom is essential for the development of reasoning and the process of acquiring meaning (Rasmussen, Yackel & King, 2004). The professor can help with configurations/teaching techniques in the classroom that encourages interaction in the group(s).

The design and use of the problems in the classroom should have the objective to promote the learning of mathematics concepts, to develop strategies, procedures and heuristics (NCTM 2000|2003). This is to say, it should have the goal that the student achieve the following: a reflexive attitude to form the structure of inference, the ability to use constructive arguing, the practice of critical reading, the use of effective writing and communication skills, and the faculty of decision making, as well as other aspects (NCTM, 2000|2003; Schoenfeld, 1985; Santos, 1997). These characteristics are necessary to form competence in students who study mathematics. Creating an environment in the classroom for the solution of problems, therefore, makes it possible to develop mathematical proficiency in students, or in other words, permit the students to acquire an aptitude for mathematics (De Corte, 2007).

Methodology

The problem described in this article forms part of a series of algebraic problems designed with the objective to understand and develop the following mathematical competencies (De Corte, 2007): an accessible base of knowledge, well-organized and flexible, the use of heuristic methods, meta-knowledge, and self regulatory skills. The development of concepts such as the unknown quantity, the variable and the solution of a linear equation were the core mathematical knowledge to be developed. The role of the professor was important in the classroom to get this objective.

The problems were implemented in a Problem Solving environment where students worked in groups to solve them. Each class session had duration of two hours. During this time, the students were given general instructions to solve a problem in separate work groups, each containing three participants. Advances were discussed at various times by the presentation of groups of students to their classmates and the class session ended with a global analysis of the problem. Finally, the homework assigned was to write an individual report demonstrating how the solution of the problem was. One of the best reports is included in this paper (figures 1-3) as an example of procedures to solve Problem 1.

The problem used for this paper was given to freshman students enrolled in a course of general mathematics, at a public university. The objective of the course was the learning of basic mathematical knowledge that students should acquire in their first year of university studies (topics of algebra, progressions, applications, probability, and statistics). The study whole group consisted of 20 students, most of whom were studying the major of commercial systems. The students level of knowledge for this group was based on their studies in high school.

The following problem was given to the students and is the one used in this paper:

Problem 1. The cost of a barrel of Maya Petroleum is \$395.00, and the cost of a barrel of Brent Petroleum is \$545.00.

a) If you mix one barrel of each brand of petroleum, how much does a barrel of this resulting mixture cost?
b) If you mix two barrels of Maya Petroleum, and one barrel of Brent Petroleum, how much does one barrel of this resulting mixture cost?
c) If you mix one barrel of Maya Petroleum and two barrels of Brent Petroleum, how much does one barrel of this resulting mixture cost?
d) If you mix 15 barrels of Maya Petroleum, and 20 barrels of Brent Petroleum, how much does one barrel of this resulting mixture cost?
e) How much should you mix from each brand of petroleum if you want the mixed barrel that you produce to cost \$450.00?
f) How much should you mix from each brand of petroleum if you want the mixed barrel that you produce to cost \$500.00?
g) How much should you mix from each brand of petroleum if you want the mixed barrel that you produce to cost \$600.00?

The questions lettered a-d can be solved in an arithmetic form. The aim is to offer students the opportunity to observe the relationship among data and identify a pattern in the structure of operations. The questions lettered e, f, and g require the structure of the following linear equation:

$$\frac{395x+545y}{x+y}=b \qquad \text{equation (1)}$$

In the above equation, the letter x corresponds to the number of barrels of Maya Petroleum, and y corresponds to the number of barrels of Brent Petroleum. The letter b corresponds to the cost of one barrel of the mixed petroleum.

Results and Discussion

It is important to emphasize some of the difficulties that were identified in students' mathematical skills at the beginning of the course when they solved word algebraic problems. Students were not aware that an equation could have an infinite number of solutions. Furthermore, they had not had previous experience in using both graphic and algebraic procedures for solving a word problem.

Students had a lot of difficulty in interpreting verbal language to algebraic language. They had difficulties in identifying the variable and writing equations. When they resolved a problem, they did not specify the solution in their report (as observed in Figure 2). In other words, they did not consult the word problem in order to analyze the viability of the solution. They only displayed the solution or solutions identified, without specifying the relationship between the solution and the question stated in the word problem. Students did not demonstrate the habit of validating their steps in the process of problem solving.

Taking the previous observations into consideration, the following aspects were developed throughout the course. Regarding accessibility, well-organization, and flexibility, mathematical concepts such as the variable, an equation, the solution of a linear equation and others were studied in depth. Concerning heuristic methods, the use and integration of different forms of representation was promoted. As for self-regulation skills, students expressed their ideas through discussions, argumentations, and presentation activities. Additionally, students were constantly reminded to validate their own procedures. They were also reminded to continuously go back and review the initial question stated in the word problem.

Procedures for solving Problem 1

Arithmetical Procedures: Looking for Patterns

Students read in groups the Problem 1. They did not have difficulties to answer the four questions *a*, *b*, *c* and *d* because of their arithmetic nature (Figure 1). However their procedures were not organized in a systematic way when they solved it in the classroom. It is possible to observe that there is a specific order and explanation of ideas in Figure 1 since this figure is part of a final report. Students could systematize the information as a homework because they had already had discussions in the classroom.

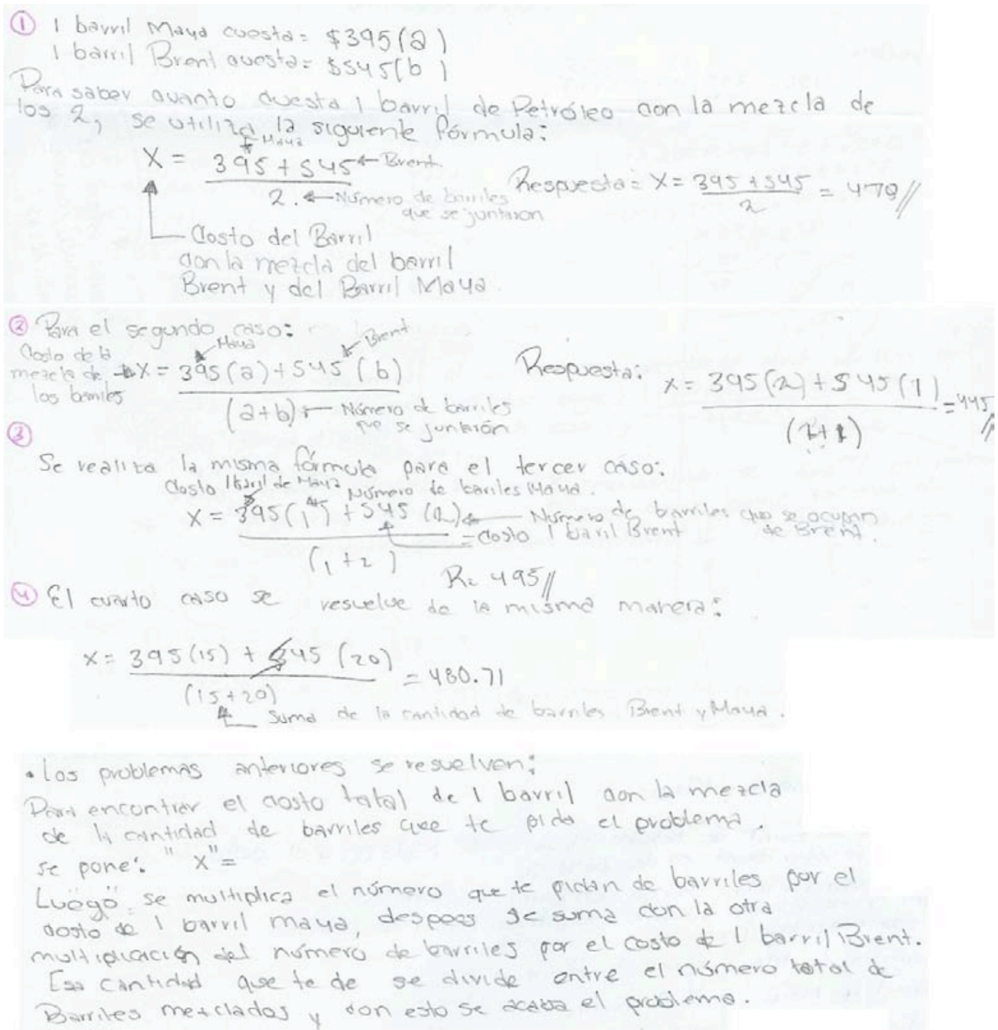

Figure 1. Process of finding the solution to *a-d* in Problem 1.

When answering the question *e* in Problem 1, groups of students tried to solve the problem using trial and error procedures. The students chose possible amounts of barrels (x and y in the equation 1) as solution, and carried out the corresponding operations. They then saw how to get closer to the answer they needed (450), and then did the calculation again.

The students demonstrated understanding of the relationship between the data in Problem 1, the structure of the relations included, and the dependency between the amounts they needed to calculate. Nevertheless, they did not consider writing this functional relation in algebraic language to solve the Problem 1(Letter *e*). This procedure was an arithmetic one.

Algebraic Procedures: Writing Equations and Using Different Mathematical Representations to Solve Letters e-g, Problem 1, and Understanding the Solution

The role of the professor in the classroom was important in this stage. The questions that the professor asked the groups to discuss the procedures were: Was there any other method that you could have used that would have helped you find the solution? Which operations were used that allowed you to answer the previous questions? What were the amounts that did not change in every calculation, and which were the amounts that varied? Can you write equations? These questions and the fact that three groups presented their organized arithmetic procedures used helped the class to utilize algebraic language and write the equation $\frac{395x+545y}{x+y}=450$ (equation 2). However, to find the answer of the problem using this equation became a challenge again. The students had only one equation with two variables so they were confused about the solution.

Professor intervened again in the classroom to promote discussion. She asked some questions as follows: What is the solution or solutions for this equation? How can we find them? How can we know what the values are for x and y? What happens if we suppose that x has a value of one, and we substitute this value in the equation. Can we find the value of y? What happens if I give different values to x? What happens if I graph them? The students were encouraged to use different representations to solve Problem 1, Letter e (Figure 2).

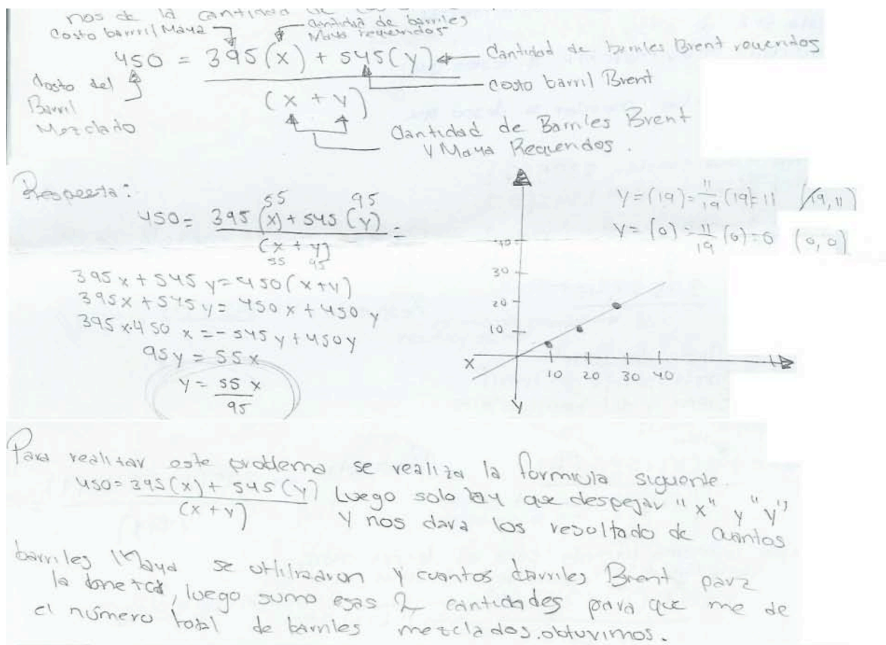

Figure 2. Process used to answer Letter e, Problem 1.

Nevertheless, it is possible to note that students were confused in the following entry (it is a translation from the text included in Figure 2): “To complete this problem, use the following formula. Later, you only have to find the value of x y y to get the results of how many barrels of Maya Petroleum and how many barrels of Brent Petroleum you will use for the mixture. Later, I can add these two quantities to give me the total number of barrels that are mixed [that] we obtained.” It is not clear if the students understood the equation used to find the solution, either the solution. The student (in this entry) was trying to explain the formula, but the student did not write something about the solution of the Problem 1. Student did not write the conclusion emerged in the classroom. The whole group presented the same difficulties in the reports.

Finding the solution to Letter f was somewhat easier for the class during the session. The whole group was able to discuss it with sufficient interpretation of the graph. During the class discussion, students found that there were an infinite number of solutions, and they obtained some of them from the equation but in the reports students did not write something about the solution as in the report of Figure 3. Students only registered the quantities used to draw the graph. Some of them explained in their reports that they followed the same process as before (in

Letter *e*), only that they changed the quantity of 450 in the equation. They explained that this modified the problem, but did not describe how this happened.

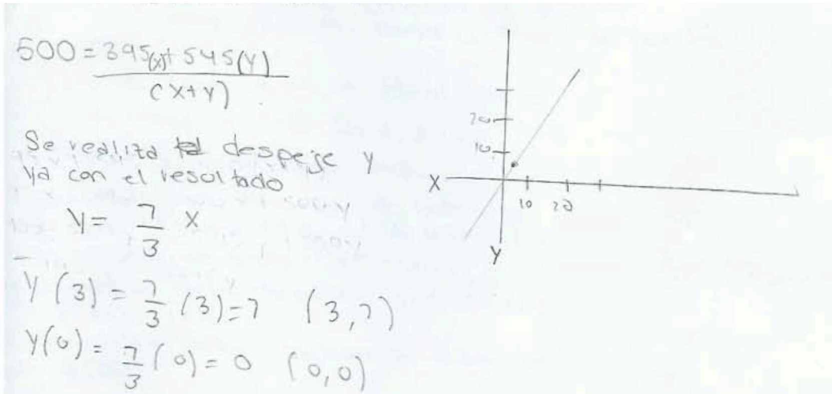

Figure 3. Process of the solution in Problem 1, Letter *f.*

When solving Letter *g* (Figure 4), the groups of students expressed surprise and asked: What is the significance of a straight line such as this? Can we talk about the negative quantities for barrels of petroleum? Is there a solution to the problem? These questions provided an advantage to discuss if there were limits in how many prices were possible for a barrel of petroleum of whatever mix we could produce. This in turn raised the question, "When can the Problem 1 have a solution?"

Students used graphs again to analyze the question of Letter *g*, Problem 1. In Figure 4 we can observe the procedure to solve it. The student in this report explained in it that in order to get the answer, he only needed to change the quantity of 600 in the equation (2). Then, the student said about the solution: "Since it gave me a negative answer, the equation doesn't have a solution."

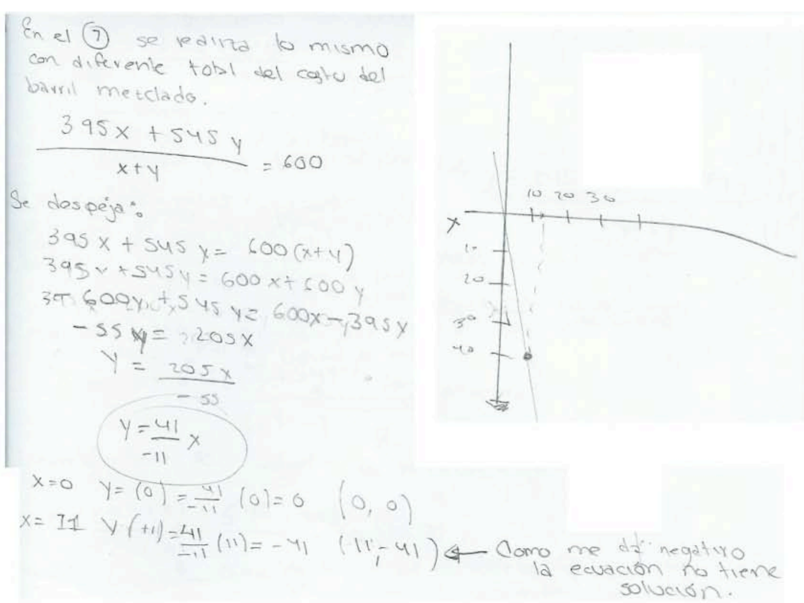

Figure 4. Process of obtaining the solution for Problem 1, Letter *g*.

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

Discussion of Results and Conclusion

In an attempt to discuss the process used to answer the problem stated previously, it is necessary to analyze the following questions, which underlie this paper: What mathematical competencies are exhibited at the superior educational level to solve problems that require linear equations? Another question is: What type of interventions can the professor use to help his students develop mathematical knowledge and competencies?

Because the procedure used in this report represented the reports of the whole group of students, it could be said that it reflects the following: the students have a base of arithmetic knowledge that permits them to undertake algebraic problems, identify information in the problem, and recognize patterns and relationships. However, they have difficulty representing these relationships in equations. They also have difficulties with the concept of infinite number of solutions, the variable, and finding the solution to an equation. They do not have different heuristic methods formed to help them solve problems. Students have impediments with argumentation and validating their own procedures and solutions. Their concept of a linear equation is one that is limited to identifying only one answer, and does not include the existence of infinite number of solutions, or non existence of any solution.

On the other hand, in the report that has been included in this paper (figures 1-4), one can note great achievements in how many mathematical competencies have been developed by the students which is demonstrated by their knowledge of the unknown quantity, the variable, and in the solving of an equation. The results are presented in an organized form; there is evidence of relationships and patterns in Figure 1, as well as in figures 2-3, even though there is no evidence of a written argumentation for the solution of the problem. That is to say, there is not a conclusion in terms of what was discussed at the end of the class: When will the Problem 1 have a solution?

The questions asked by the teacher helped students reflect on the concept of solution and its relationship with other concepts, such as the unknown quantity and variable. Integrating the process of graphing in the process of solving the equation helped students to learn these concepts in depth. The role of the professor was essential in this sense, as well as proving help to the students to reformulate, contextualize, discuss, and analyze Problem 1. Constantly monitoring the procedures used by the groups was important to identify the mathematical knowledge of the students, the comprehension level of the problem, and the formation of pertinent questions.

This problem was implemented in other classroom settings, beyond the one discussed in this article. The class discussed the type of solutions they could use in order to solve the problem in terms of whole numbers and real numbers, as well as their significance in terms of barrels, and the possibility of having the a container to form the mixture. Students identified that the total amount of the mixture obtained would be limited to only one barrel, and therefore, as it is expected, other types of graphics and discussions surfaced.

NAÏVE MENTAL MODELS: THE PERSISTENCE OF PROSPECTIVE ELEMENTARY TEACHERS' CONCEPTION OF PROPORTIONALITY

Lingguo Bu
[1]Southern Illinois University Carbondale
lgbu@siu.edu

Erhan Selcuk Haciomeroglu[2]
University of Central Florida
Erhan.Haciomeroglu@ucf.edu

Using dynamic learning technologies, we created dynamic conceptual models to address prospective elementary teachers' misconception of proportionality involving problems in the form of "a/b of X". Data collected at multiple points revealed the persistence of prospective teachers' naïve mental models and their interference with meaningful mathematical reasoning.

Learning is fundamentally about change, and change has been emphatically called for during the past two decades in mathematics education, where rule-based instruction masks the true nature of mathematical reasoning and hinders young students' academic progress and career opportunities (National Council of Teachers of Mathematics, 2000). There is growing evidence that, for a variety of reasons, many elementary school teachers do not have the kind of mathematical knowledge that is pedagogically conducive to meaningful classroom instruction (e.g., National Council on Teacher Quality, 2008). Teacher preparation programs and professional development projects have thus resorted to inquiry-based and theory-guided instruction in order to bring about substantive changes in K-12 teaching practices. Following the work of Milrad, Spector, and Davidsen (2003) and Seel (2003), we incorporated model-centered instruction into a mathematics methods course in our teacher preparation programs, taking advantage of emerging open-source dynamic mathematics technologies. We embedded significant mathematical topics in realistic situations and made connections with other focal ideas in a coherent manner, integrating multiple representations and dynamic modeling tools. In this paper, we document our research findings about prospective teachers' misconceptions as they interacted with a dynamic conceptual model specifically designed to explore their understanding of ratio and proportion. We analyze their responses under the perspective of mental models and discuss the implications for mathematics teacher preparation.

Theoretical Framework

We conducted our instructional intervention and data analysis under the theoretical perspective of Model-Centered Learning and Instruction (MCLI, Seel, 2003). Mental models are dynamic mental structures that learners create internally in support of inference and decision-making when they are faced with a problem situation. Cognitively, mental models build a bridge between propositional rules and perceptual images as a means of comprehension (Johnson-Laird, 1983). The interpretation of a problem or a discourse is a result of both the model and the processes that have led to the construction of a model. As Johnson-Laird contends, there is no need for mental logic in the theory of mental models and "people do not ordinarily think in a truthful-functional way" (p. 51). In our effort to make sense of prospective mathematics teachers' naïve mental models for fundamental ideas in school mathematics, we find the theory of mental models well suited for our purpose and MCLI an informative instructional design framework for reconsidering the teaching and learning of school mathematics in teacher preparation programs. Furthermore, conceptual modeling is one of the instructional strategies that can potentially support prospective teachers' creation of valid mental models as conventionally accepted in the field of the subject matter (Norman, 1983; Seel, 2005).

Methods

Context and Participants

This study was part of a mathematics content and methods course in the teacher preparation program at a state university in the Midwestern United States. The class met once a week in a computer lab and three times a week in a regular classroom for 50 minutes. Throughout the semester, the instructor adhered to mathematical modeling as an umbrella perspective on mathematical problem solving involving key topics in middle grades mathematics. Key theoretical constructs were shared with participants using specific examples from school mathematics, including schemata, mental models, modeling, and simulations. Multiple representations were introduced using the open-source mathematical environment GeoGebra (Hohenwarter & Hohenwarter, 2009).

There were 16 students who stayed through the semester; 14 of them gave consent to the study. They were freshman college students with an intention to major in the elementary education program, which requires them to be enrolled in the course. There were only four male students in the class. Most students had a neutral or negative attitude toward mathematics as shown in the institutional evaluation form.

Data Collection

During the first half of the semester, the instructor realized through quizzes and daily interactions with the participants that the majority had a rather rule-based knowledge of elementary mathematics, which was very consistent with the literature (Stigler & Hiebert, 1999). One area that most students were struggling was proportional reasoning, which required the coordination of several variables (Lesh, Post, & Behr, 1988). Therefore, on the mid-term exam, the following problem, among others, was given: *Please explain why "15% of 200" can be written as 15% × 200?* Surprisingly, no one was able to give a mathematically valid and reasonable explanation. The common response was "Because in math terms, '*of*' means *to multiply*. And the multiplication symbol in mathematics is (×)". The rest were more or less the same, with a few students adding more irrelevant comments such as "one cannot divide because that would make the number bigger."

It thus became evident that the majority of the participants held a naïve mental model of the proportional situation that led them to the superficial inferences, namely, symbolic word matching. There is no mathematical or pedagogical meaning in this kind of mental model, albeit it could produce correct numbers and seems meaningful to the participants.

To address this common conception held by virtually all the participants, a web-based dynamic conceptual model (see Figure 1) was designed using GeoGebra to demonstrate the structural relationship underlying the problem: *A% of Y* essentially means finding a number *X* such that *A* is to *100* as *X* is to *Y*. The conceptual model allows the exploration of similar problems and was discussed in class and uploaded to the course site. As observed in class, all participants seemed to accept the mathematical structure of the conceptual model as a reasonable way to explain "*why 15% of 200 can be found by 15% × 200.*"

After a month, a similar problem was given on a quiz, involving a fraction instead of a percent. A brief summary of the quiz was subsequently given to the whole class. After another month, two versions of the problem were given on the final exam, one involving a fraction at the beginning of the test and the other a percent at the end. With the second one, the conceptual model was printed on the test form and participants were asked to respond in reference to the model.

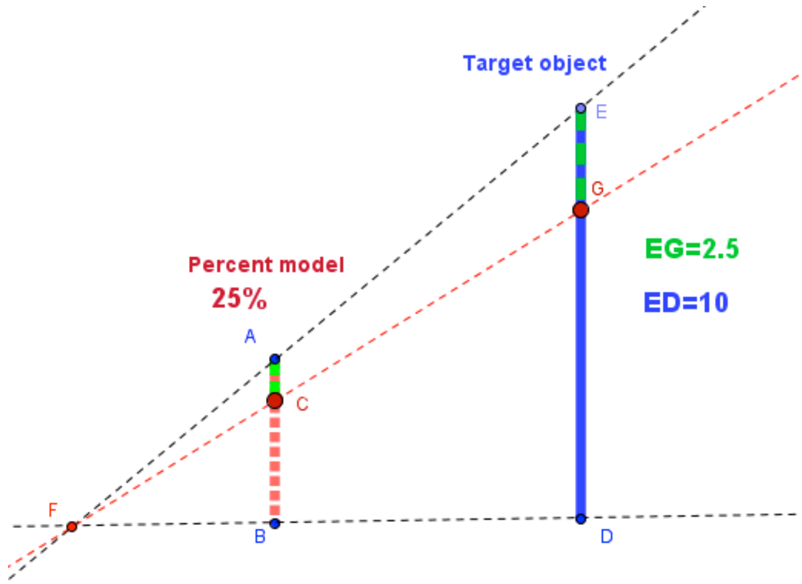

Figure 1. A dynamic conceptual models for problems in the form of "a/b of X"

Results and Discussions

Data collected at three points converged uniformly to the persistence of participants' preconceived mental models of the problem situation. The dynamic conceptual model failed to bring about significant changes to the way the participants would deal pedagogically with such problems. Only one-third of them started to refer to the conceptual model when it was presented along with the problem. For example, in response to " why *23%* of *57* can be found by *23%* × *57* ?", two participants wrote as follows:

Student A: You are able to do this because the following model set up a scale where your slider configures how much you view when taking a percent (or partial part/fraction) of a whole number (ex. *57*). In other words, percent is a fraction or part of the whole number you are using. This kind of set-up is called a proportion. It would be the same as the equation: *x/57= 23/100*.

Student B: Say *ED=57*. Follow the projected path of *23%* to *57*. Find where the path intersects at two points on *57*. That is *23%* of 57. Multiplying *23%* × *57* would get the same answer.

Findings of this study confirm Seel's (2003) observation that students do not always accept the conceptual models presented in model-centered instruction; instead, they create mental models on the fly in response to a specific situation, which is not necessarily consistent with the instruction they received. This, however, does not mean that students did not create, at least, a transitory valid mental model while interacting with the conceptual model. It does imply that on the one hand, mental models are not fixed mental entities and, on the other hand, certain naïve mental models are very resistant to changes (cf. Perkins, 1986; Schoenfeld, 1985) and thus may call for the use of mental censors, especially in teaching practice. It is worth noting that when conceptual models are given, some participants tend to respond in more meaningful ways. Further studies are needed to explore if such conceptual models can bring about long-term changes in participants' mental models with respect to this type of problem or similar problems in school mathematics. As web-based interactive and dynamic learning environments enter all levels of mathematics education, this study contributes to the literature of model-based learning and instruction (Doerr & Lesh, 2003; Zbiek & Conner, 2006) and identifies needs for future design and development, especially in teacher education.

This study sought to understand the similarities and differences between middle and high school students' methods for generalizing linear patterning tasks. While high school students in Algebra 2 performed much better than middle school students, the success rate remained low. Whereas middle school students frequently applied proportional reasoning on such tasks, high school students favored a linear strategy. Individual interviews with 24 students in grades 6-8, Algebra 1, and Algebra 2 uncovered many conceptual difficulties for generalizing the linear pattern.

Objectives

Pattern generalization has been acknowledged as helping students transition from early algebra to formal algebra (Bezuszka & Kenney, 2008; Department for Education and Skills, 2001; English &Warren, 1998; National Council of Teachers of Mathematics [NCTM], 2000; Usiskin, 1988). Some studies (Cooper & Sakane, 1986; Lannin, 2005; Steele, 2008; Stacey, 1989) have focused their attention on investigating students' abilities and strategies to generalize and justify patterns presented in a geometric context and have suggested that the visual aspect of the geometric structure helped students identify the patterns of change and facilitate the generalizing process.

However, the participants of all these existing studies were middle school students prior to taking formal lessons in algebra. It is yet unknown how high school students, after having taken Algebra 1 or Algebra 2 classes, would perform on geometric generalizing activities and whether their strategies would be similar to or different from those of middle school students. Would they be more likely to approach this type of task by generating a rule, creating a table, or applying the concept of slope and *y*-intercept? This proposal reports partial findings of a study that investigated the rate of change concept with both middle and high school students. In particular, this report discusses middle and high school students' performance and their methods used in solving a linear geometrical patterning task (Figure 1) and the conceptual challenges they faced when attempting to generalize this pattern during the follow-up interviews.

Growing Dots Task

How many dots will be in the 100th picture? Show your work.

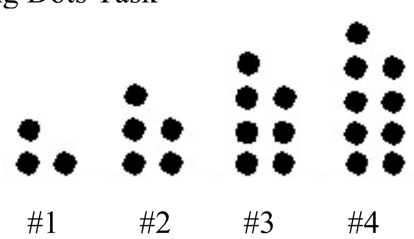

Figure 1. A linear geometric patterning task

Specifically, we seek to answer the following two research questions:

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

1. What methods do middle and high school students use to solve a linear patterning task, and what are the similarities and differences of methods between the middle school and high school students?
2. What conceptual challenges do middle and high school students face when generalizing a linear patterning task, and what are the similarities and differences of these challenges between the middle school and high school students?

Theoretical Framework

Blanton and Kaput (2005) describe "reasoning algebraically" as a "process in which students generalize mathematical ideas from a set of particular instances, establish those generalizations through the discourse of argumentation, and express them in increasingly formal and appropriate ways" (p. 413). Students are expected to be proficient in developing two types of generalizing rules by the end of their algebra learning: recursive form or the close form (NCTM, 2000). For example, the rule of the recursive form for the Growing Dots task could be expressed as Next = Now + 2, starting at 3, where Now and Next represent the number of dots in the current and next stages. The rule of the close form can be expressed as $y = 1 + 2x$, where x represents the stage of the figure, and y represents the number of dots in that figure. There is a growing recognition that the development of algebraic reasoning is a long-term process that needs to be started at the elementary school level.

Linear numerical and geometrical (visual) patterns are among the ones that have been used most frequently at the elementary and middle school levels to lay the foundation for algebraic reasoning**.** Prior studies have identified many conceptual challenges students face when asked to represent a general rule in symbolic forms, as well as the difficulties they experience in connecting the recursive and close form (Lannin, 2005; Rivera & Becker, 2008). Stacey (1989) conducted a paper-and-pencil test to investigate the strategies used to solve three linear generalizing problems by students aged 9 to 13 years old. She found that the majority of students found generalizing to be challenging. The rate of correct responses varied from 8% to 24% for various age groups. Her analysis identified four main methods of solving this type of task (Table 1). This work was used as the framework for our initial coding, with new ones being added as needed.

Method	**Stacey's Explanations**	**Examples from the Growing Dots Task**
Counting	Counting from a drawing	"I used a calculator, started with the last number, added 2, until I got to 100."
Difference	Multiplying the figure number by the common difference 2, i.e., implicitly assuming that repeated addition of 2 implies that $M(n) = 2n$	"It went up by 2, $2 \times 100 = 200$"
Whole object	Taking a multiple of the number of squares in an earlier figure, i.e., implicitly assuming that $M(nm) = m \times M(n)$	"There were 3 dots in number one picture. $3 \times 100 = 300$"
Linear	Using a pattern that recognizes	"$1 + 100 \times 2 = 201$" or "$3 + 100 \times 2 =$

	both multiplication and addition are involved and that the order of operation matters; i.e., implicitly using a linear model $M(n) = an + b$ with $b \neq 0$.	203"
Unclassified		$3 \times 5 \times 7 \times 9 \times 11 = 10{,}395$

Table 1. Explanations of common student methods with Stacey and Growing Dots Task

Methods

Participants

The study was conducted in a rural school district in a Midwestern state of the United States. The district had only one middle school (grades 6-8) and one high school (grades 9-12) with about 650 and 840 students, respectively, in 2010. The student population was 80% non-Hispanic White and 11% Black. Fifty-one percent of the students received free or reduced lunch. Both middle and high schools had student test scores on state mandatory tests close to the state means. Both schools used mathematics curriculum from McDougal Littell. Students from grade 7 and above had studied units in terms of either linear equation or linear function in their mathematics classes prior to the start of the study.

Procedures

A paper-and-pencil test was administrated at the end of the school year in the spring of 2010 during the regular math class. One hundred pairs of parents/students gave consent to have their student data included in the study. The numerical break-down of these 100 students by class can be seen in Table 2 below.

The test had three main sections that contained tasks embedded in various patterns of change, such as linear, piece-wise linear, exponential, and quadratic. Based on the written work, 24 students (5 sixth graders, 4 seventh graders, 4 eighth graders, 5 Algebra 1 students, and 6 Algebra 2 students) were interviewed individually for 45-60 minutes to gain more in-depth knowledge of their mathematical reasoning on how they solved the tasks on the written test. When there was an error on the written test, probing questions based on the nature of the errors followed to help students clarifying their reasoning. Then they were asked to find another method to solve the given problems. The interviewer encouraged students to think aloud while developing their alterative methods.

In this paper, we will focus on only the results of the task in Figure 1 and the portion of the follow-up interviews that aimed at identifying the various conceptual difficulties students had in generalizing the given linear pattern. Generally speaking, the interviewer first asked students to describe the pattern they saw in words or in numerical expressions. Then the interviewer asked the students to justify their pattern by connecting it to the pictures. In addition, the high school students and a few advanced middle school students were encouraged to find a "formula" that would help them solve the question in general. If the students seemed to be lost, the interviewer encouraged them to generate a table or graph to help them identify the correct formula.

Data Processing and Analysis

The students' tests were first graded for the correctness of the final answers, then coded with the types of strategies developed by Stacey (1989). First, two individuals coded the data independently. Then they compared the codes and conducted further discussion to resolve the discrepancies. All interviews were transcribed with the help of Trasana© and analyzed to deepen our understanding of the reasoning behind students' methods and the sources of the misconception or partial understanding that prevented them from identifying the correct general rule.

Results and Discussions

In this section, we will first discuss the results and findings regarding students' performance on the task, methods they used to solve this task on the written test, and a comparison of the variance between middle and high school students. We will then report the findings based on the analysis of the follow-up interviews.

Methods for Solving the Task

Table 2 shows how the participating students performed on this study, organized by their grade/course level. Overall, the performance level was low across the grades, and significantly lower than those being reported in Stacey's study. There is a general trend of improvement over the grade/course levels, with the Algebra 1 students being the exception.

	Grade 6 (n = 19)	Grade 7 (n = 20)	Grade 8 (n = 22)	Algebra 1 (n = 20)	Algebra 2 (n = 19)
% of correct responses	5%	0%	13.6%	0%	26.3%

Table 2. Student performance on the pictorial linear problem

Similar to Stacey (1989), we also identified four methods in this study presented in the students' written work. However, our analysis found more complexity of student reasoning within the three most commonly used methods (Whole Object, Linear, and Counting/Estimating, referred to as Counting by Stacey), than was presented by Stacey. Whole Object was one of four methods (shown in Table 3) used frequently to find the number of dots in the 100th picture. Four different types of reasoning were identified in this category. The student multiplied the number of dots in the existing diagrams by 100, which is the term in the sequence for the 100th picture, such as 3 × 100 and 9 × 100, where 3 and 9 represent the number of dots in the 1st picture and 4th picture, respectively. Another group of students used the number of dots from the existing diagrams multiplied by the quotient of 100 and the figure number of that diagram. For example, a student's solution to "draw pictures up to #10, and then 21 × 10" showed that the students found there were 21 dots in the 10th picture, so the 100th picture would contain 10 times as many dots. In addition, some students thought they could obtain the answer by multiplying the number of dots in a particular picture by the difference between 100 and the position number of that picture. For instance, a student reasoned that since the 4th picture has 9 dots and 100 – 4 = 96, then the 100th picture must have 96 × 9 = 864 dots.

We expanded the original Counting Method identified by Stacey (1989) to be the Counting and Estimating method, where the student had the explicit awareness of the common difference of 2, but didn't provide further explanations that would indicate that the student had used another method. Some examples of this include: "I would say 100 dots, you are adding 2 every time," "Almost 101 dots, the dots go up by 2 and if you add 2 all the way up to 50 you get 101," or one student simply put down "plus 2 each column, 103." The answers given were quite varied in this method. While they were able to recognize the constant change of 2 in the pattern, students were not able to coordinate that piece of information with the overall number of dots.

While the Linear method was used by many students, not all of them reached the correct answer. The most common false linear method assumed the initial value to be 3, the number of dots in the 1st picture, and thus students gave 203 as the answer. Three high school students gave 199 or 197 as the answer, assuming 9 (the number of dots in 4th picture) + 2*x* (95 or 96). These students recognized the need to make an adjustment for the number of 2s being added, but failed to come up with the correct adjustment.

Table 3 illustrates the variance in methods used by the different grade levels. The gray cell indicates the most frequently used method for that particular grade. Nearly 50% of the sixth graders used the Whole Object method that was based on a faulty assumption that a proportional relationship existed in the given pattern. While many of them also recognized the constant difference of 2 in the pattern, the pull for proportional relationship was very strong. The dominating strategy used by seventh graders was the Difference method, based on the constant increase pattern. The more evenly distributed methods in eighth grade and Algebra 1 students reflected the transitional stage. Finally, more than half of the students from the Algebra 2 course used the Linear method.

	Grade 6 (n = 19)	Grade 7 (n = 20)	Grade 8 (n = 22)	Algebra 1 (n = 20)	Algebra 2 (n = 19)
Whole Object	9 (47%)	4 (20%)	4 (18%)	4 (20%)	2 (11%)
Difference	2 (11%)	10 (50%)	3 (9%)	4 (20%)	1 (5%)
Counting/Estimating	3 (16%)	3 (15%)	6 (32%)	2 (10%)	2 (11%)
Linear	1 (5%)	1 (5%)	6 (27%)	5 (25%)	11 (58%)
Unclassified	4 (21%)	2 (10%)	3 (14%)	5 (25%)	3 (15%)

Table 3. Distribution of student strategies by grades

As indicated in Table 3, the nature of the conceptual challenges for middle and high school students in this study was quite different. The application of the Whole Object method by close to 50% of the sixth and seventh grade students could be seen as part of a widespread phenomenon of overgeneralizing proportionality (Stacey, 1989; Van Dooren, De Bock, Depaepe, Janssens, & Verschaffel, 2003). This could be the result of heavy emphasis on proportional reasoning in mathematics curriculum at the sixth and seventh grades. Both eighth graders and Algebra 1 students, while showing some tendency to move away from assuming the proportionality in this type of task, were not certain about the alternative methods. Fifty-eight percent of the students from the Algebra 2 course used the Linear method, which involved the coordination of two quantities—the initial value and the constant change. However, while there is an increasing awareness of these two quantities and the need to coordinate them, few were able to carry out the coordination successfully to get the correct answer of 201.

Strategies and Conceptual Challenges for Generalizing the Linear Pattern

The follow-up interviews with the 24 students selected to reflect a wide range of methods used for the paper-and-pencil test attempted to identify the roots of these conceptual difficulties.

All interviewees were encouraged to first verbally describe the pattern they saw in the picture. All recognized the "plus 2" pattern among the consecutive pictures. When encouraged to describe a way to describe the overall pattern, three different numerical patterns with four different geometrical configurations emerged (see Figure 2): (a) 3 dots plus 2 dots more each time (Pattern #1 and Pattern #2); (b) 1 dot and a pair of 2, adding a pair each time afterwards (Pattern #3); and (c) the left column has the same number of dots as the picture number, and the right column is just one more dot than the left column (Pattern #4). When reasoned correctly, both Pattern #1 and Pattern #2 led to the equation of $y = 3 + 2(100–1)$, with y being the total number of dots in that sequence. However, Pattern #3 would lead to the equation $y = 1 + 2(100)$, and Pattern #4 to $y = 100 + (100+1)$. All will lead to the answer of 201. Five out of the 24 interviewees were able to come up with the correct answers on their own. Three of them used Pattern #4 as the basis for their solutions, and one used Pattern #3. The last student saw Pattern #1, but did not use the physical configuration to generate his answer. Instead, he shifted his attention to the numerical pattern that the number of dots was about double the corresponding figure number, and he adjusted this estimation with "plus 1" to get his answer. All were able to describe the general rules in words or in symbol form, $y = 2x + 1$.

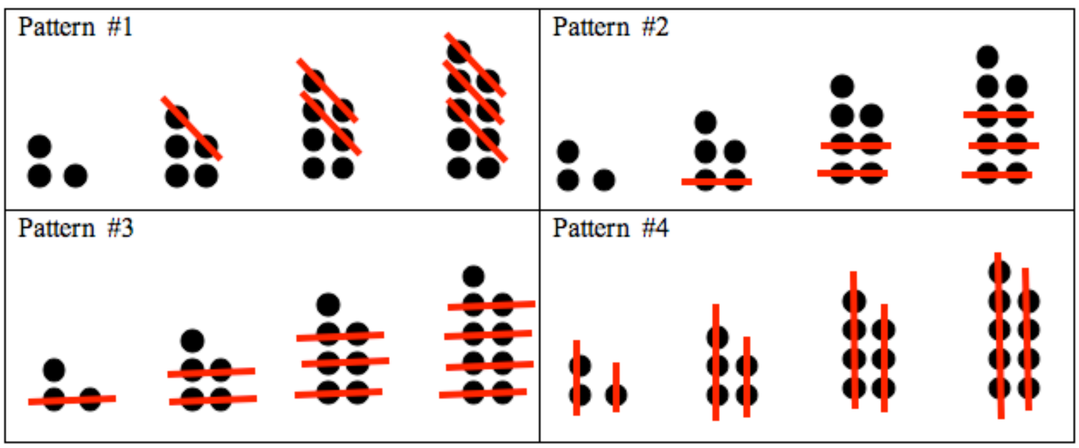

Figure 2. Students' strategies to generalize the linear pattern task

With probing questions that helped students to use available tools such as numerical expressions, graphs, or tables to make sense of the pattern they saw, 11 of the remaining 19 students were able to come up with the generalized rule in either words or symbols. In the remaining part of this section, we will discuss the conceptual difficulties students encountered when attempting to generalize with numerical expressions, tables, and graphs.

When the interviewees were unable to develop a generalized formula, they were encouraged to generate a table or a list to make the relationship between the "figure number" and the "number of dots in the corresponding figure" more explicit. To develop a generalized formula for the given pattern, it is necessarily to recognize both the "plus 2" pattern and the initial amount, which is either 1 or 3, depending on how students saw the pattern. When students failed to do so on their own, the interviewer suggested the student rewrite the 5 dots in the second set of dots either as 3 + 2 or 1 + 2 + 2, the 7 dots in the third set of dots as 3 + 2 + 2 or 1 + 2 + 2 + 2. The question then becomes, how many 2s are in each expression? There were four main conceptual challenges that the interviewees faced when attempting to find the generalized formula from this path. First, those who saw either Pattern #1 or Pattern #2 had a hard time articulating that the idea of the number of 2s being added in the figure is 1 less than the corresponding figure number. Second, some students were unable to connect repeated addition to multiplication. Third, some rejected the expression 3 + 99(2) because they read it as (3 + 99)2. Finally, some high school students were uncomfortable with the expression $3 + (x - 1)2$ because it did not fit their experience with $y = mx + b$ with the constant on the back and the variable in front of the coefficient.

Those who used a table or graph to identify the generalized formula faced different type of conceptual challenges. Out of nine students who attempted to use a table to make sense of the generalized pattern, only four succeeded. Three of these students did so after converting the table data to a graph. One made an estimate of $y = 2x$ and adjusted for it by comparing the y values. None connected the concept of constant rate of increase with the concept of slope and used it to find the correct formula. The analysis of those that were not successful suggested three main types of conceptual challenges. The first one was rooted in the limited conception of the patterning task. For example, one student explained that the 100th picture would have a different number of dots depending on which given figure you used. So the 100th picture for the 1st given picture would be 300, and the 100th picture for the 4th picture would be 900. The second challenge was caused by the difficulty shifting from the recursive pattern which existed in the number sequences formed by the number of dots in the picture, and the close form which asked for the relationship between the position number in the sequence and the number of dots in the corresponding picture. They believed that $y = x + 2$ was the correct answer. The last conceptual challenge was the false assumption of proportionality. In addition to the Whole Object method, some students believed that there was a constant multiplicative factor between the variables x, the figure number, and y the number of dots in the corresponding figure. For example, one student thought the equation would be $y = 2.5x$ because there were 5 dots in the 2nd picture, but then noticed right away that this formula would not work for the 3rd picture. When urged to check if the proportional pattern holds for the first four given figures, all students were able to see that the y=mx equation they proposed did not work.

Implications and Significance of the Study

The findings of this study indicated that geometrical patterning tasks are accessible and challenging to both middle and high school students. The availability of geometrical figures in the pattern helped to ground students' explanations of their methods and reasoning. Many research studies have reported the strong tendency for students to apply the cross-multiply algorithm indiscriminately which, unfortunately, is a side effect of the increased emphasis on proportional reasoning at the middle school level. Comparing and contrasting geometrical patterns that have zero and no-zero value in stage one can highlight the essential characteristics of linear versus proportional relationships. This type of task provides a natural setting to make distinctions between proportional and nonproportional relationships. The experience of using and interpreting complex numerical expressions is crucial to students' work with algebraic expressions. The findings of this study affirmed the potential of geometrical patterning tasks to help students develop algebraic reasoning as suggested by Lannin (2005) and Steele (2008).

The overall low performance of the participating students was a surprise to both the researchers and the mathematics teachers of these students. The follow-up interviews conducted with the students have led to the identification of the several conceptual challenges faced by students when attempting to generalize the patterns. Such information is useful in developing hypothetical instruction paths that would be effective to support students with different initial methods for this type of task.

The findings also suggested that while geometrical patterning tasks might be beneficial in helping students develop algebraic reasoning, such development is a complex process. Even though all the Algebra 1 and Algebra 2 students interviewed in this study have learned about linear functions, none of them used the concepts of slope and intercept to help them identify the general rule of this patterning task. The tendency to focus only on the change in y-values rather than on the rate of change that relates x and y values suggests the need of additional instruction on this important concept. Future studies are still needed to explore how geometrical patterning tasks might be used to assist students in developing a more robust understanding of the rate of change as a main conceptual tool to differentiate linear and nonlinear relationships.

This study examined the development of thirty-seven elementary and middle grades teachers' algebraic connections and representational fluency during a six-month professional learning project. To evaluate the collaborative nature of designing professional development, the team of professional developers/researchers used the collective self-study method (Samaras & Freese, 2006) to examine how purposively designed experiences such as the content-focused institute in the summer with school-based follow-up Lesson Study cycles (Lewis, 2002) in the fall encouraged vertical articulation of algebraic connections. The analysis of teachers' reflections from problem solving tasks and Lesson Study and researchers' memos from observed research lessons revealed more flexibility in teachers' representational fluency with problem solving strategies in the classrooms.

Introduction

Research and initiatives in elementary and middle school mathematics emphasize the importance of both fostering algebraic reasoning through problem solving and laying the critical foundations before students encounter formal algebra instruction (Blanton, 2008; Driscoll, 1999; NCTM, 2000; NMAP, 2008). This leads to some important practical questions: what experiences are required for elementary and middle grades teachers to effectively teach algebraic reasoning through problem solving, especially if they never learned mathematics in a reform oriented manner? What opportunities can professional development providers design for teachers to develop teachers' representational fluency? Reform oriented mathematics teaching presents challenges as teachers learn to change their practices (Remillard, 2000; Boaler, 1999). Such changes that advocate a reform-based vision of teaching algebra along with the great need for effective algebraic instruction in the K-12 curriculum has motivated mathematics educators, mathematicians and school leaders to emphasize more on studies about teachers' understanding of algebraic thinking and reasoning. Teaching algebraic reasoning in the earlier grades through problem solving requires depth of mathematical content knowledge for teaching. Hill, Sleep, Lewis and Ball (2007) suggest that specialized content knowledge is partially domain-specific and that the specified content knowledge for mathematics is not obtained based on an intelligence level, or ability to understand mathematics. Mathematics knowledge for teaching (Hill et. al, 2007) includes understanding of general content but also having domain specific knowledge of students and knowledge of content in algebra, patterns, and functions.

The purpose of the study was to provide a coherent picture of how teachers' algebraic connections and representational fluency develop through a content focused and practice-based professional development project. Our study set out to identify the key practice-based skills necessary for teachers to acquire the specialized knowledge for early algebra that would help them make algebraic connections to enhance their teaching and promote algebraic thinking in students.

Theoretic Framework

"Early algebra is not the same as algebra early. To move algebra-as-most-of-us-were-taught-it to elementary school is a recipe for disaster" (Carraher, Schelimann & Schwarts, 2008, p. 235). The notion of teaching early algebra then is both a paradigm shift and a novel way of teaching that requires extensive professional development. According to Carraher et al. (2008), early algebra builds on background contexts of rich problems where early algebra tightly interweaves existing topics of early mathematics and formal notation is introduced gradually and "judiciously". Many researchers have explored teaching early algebra for the elementary grades and found that elementary students are capable of reasoning algebraically (Kaput, Carraher, & Blanton, 2008; Kaput, 2008; Bastable & Schifler, 2007; Kieren, 2004; Carpenter & Levi, 2000; Greenes & Findell, 1999; Moses, 1993). This integrative approach of algebraic reasoning and arithmetic connections is common in many international elementary and middle school mathematics curriculum (e.g., China, Russia, Singapore, and South Korea), where students begin the formal study of algebra much earlier (Cai, 2004). Such integrative approaches have helped these students in building mathematical understanding with skill development, in embedding the arithmetic in interesting and challenging problem situations, in enhancing their number sense through purposeful calculations, and in relating problems to one another and to other essential mathematics content knowledge they are building constantly.

According to the NCTM (2000) the underlying concepts of algebra are patterns, relations, and functions and the way in which they are utilized to: 1) represent and analyze mathematical situations and structures using algebraic symbols; 2) represent and understand quantitative relationships; and 3) analyze change in various contexts (NCTM, 2000, p. 39). Blanton and Kaput's (2008) Generalizing to Extend Arithmetic to Algebraic Reasoning (GEAAR), project goal was to embed algebraic thinking into instruction and to build teacher capacity to "algebrafy their classrooms" (p. 384). The evidence to support their findings was gathered from teachers' reflections and written work, students' reflections and written work, observations, and interviews. This professional development addressed both teacher content knowledge as well as classroom practices. Blanton and Kaput (2008) reported that teachers become better at teaching algebraic reasoning when the teachers' own mathematical knowledge and understanding are increased. According to Blanton and Kaput (2008), teachers develop their algebra "eyes and ears" which allow them to bring out the algebraic reasoning while looking at student work and carefully listening to their discussions and questions. This requires teachers having an integrated depth of algebra content knowledge to know what to look and listen for in the classroom. Developing algebraic habits of minds (Driscoll,1999) include the idea of seeing algebra as: 1) doing and undoing; 2) building rules to represent a function; and 3) abstracting from computation. Developing algebraic habits of mind is critically important to the success of our elementary, middle and high school teachers. It takes a teacher who has a deep and profound understanding of fundamental algebra to provide opportunities for elementary and middle grades students to explore the foundation concepts for algebraic reasoning through patterning, relations, functions, and representations using algebraic symbols and utilizing mathematical models to represent relationships (NCTM, 2000).

For our study, we defined 'algebraic connection' as the integrated knowledge developed by applying algebraic concepts to interdisciplinary problem-solving opportunities through multiple representations and flexible strategies. Such connections help to discover and comprehend the applications of mathematical concepts to real-world problems in a way that is beyond what is taught in a traditional classroom. Thus, 'algebraic connection for teachers' included some very specific practiced-based skills (such as, making: 1) cross-curricular (horizontal) connections- algebraic connections to real world situations and interdisciplinary problem-solving; 2) 'algebra-arithmetic' (vertical) connections- connecting arithmetic structures such as addition, subtraction, multiplication, division, ratios, proportional thinking, rational numbers and geometry to algebra; making generalizations about a concept; 3) algebraic connections through representations orchestrating mathematics discussions through the use of students' physical, tabular graphical models, verbal and symbolic notations to build representational fluency.

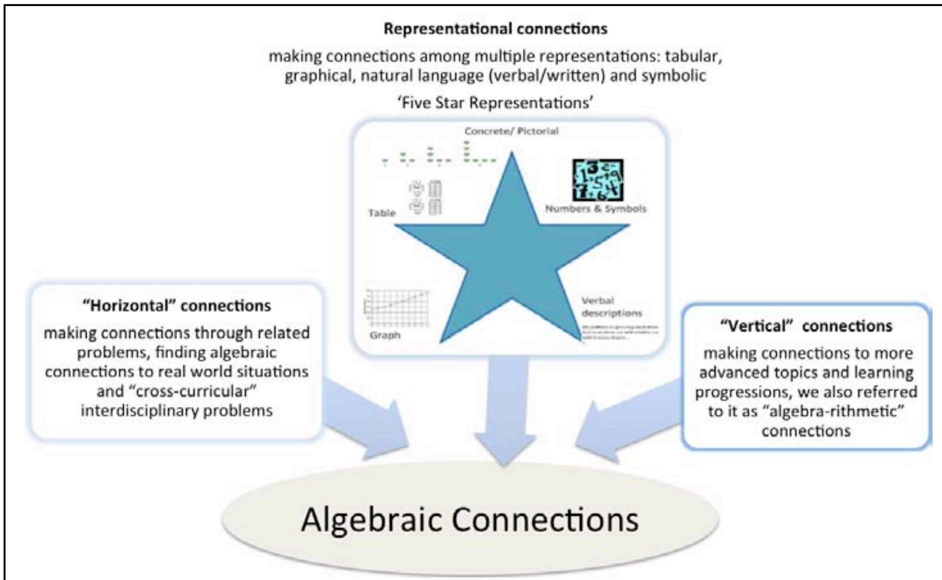

Figure 1

One of the key performance skills was for teachers to teach algebraic lessons using the five star representations for all algebra lessons. The five star representation connected representational systems such as using pictures, number lines, graphs, tables, arithmetic notations and verbal description. (Figure 1) Representational fluency, the ability to use multiple representations and translate among these models, has been shown to be critical in building students' mathematical understanding (Goldin & Shteingold, 2001).

Methods

Research Questions

The goal of the study was to understand the processes of change in participants' teaching practices and examining what professional development activities and events were pivotal in influencing that change. This study explored the following two research questions: 1) what changes in teachers' development of the algebraic connections were evident through the activities and professional learning opportunities and 2) what are some essential professional development opportunities and support necessary for teachers as they transition into teaching through problem solving and making algebraic connections?

Data Sources

This study examined teachers' reflections and field notes from two phases of the professional development project: the summer institute where teachers were immersed in algebra problem solving activities as learners and the second phase with the follow-up Lesson Study where teachers implemented teaching practices that promoted algebraic connections through rich problem solving.

Participants

Thirty-seven elementary and middle grades teachers from grades 3 - 8 met for a one week summer institute and continued as school teams in Lesson Study (Lewis, 2002) during the academic year. A majority of the teachers (78%) taught in Title One schools that served underrepresented and underserved populations. On average, teachers had 12 years of experience, where 18 held baccalaureate degrees and 19 held Master degrees. Six teachers were mathematics specialists, and three teachers were special educators.

Procedures

To evaluate the collaborative nature of designing professional development, the team of professional developers/researchers used the collective self-study method (Samaras & Freese, 2006) to examine how purposively designed experiences such as the content-focused institute in the summer with school-based follow-up Lesson Study cycles in the fall encouraged vertical articulation of algebraic connections. The method for analysis involved a mixed method approach of survey analysis and qualitative analysis. Using the Grounded Theory approach (Strauss & Corbin, 1994), we used a constant comparative method. This method allowed for us to systematically gather and analyze data through the summer institute and Lesson Study cycle and to generate a theory that was grounded in these data. The researchers used Self-Study to determine what designed activities promoted the development of representational fluency. During the summer and follow-up Lesson Study session, we debriefed on the project activities and analyzed the teachers' reflections from the activities. Upon analysis, we searched for recurring themes and categories that linked various data. The analysis of the data from teacher reflection began with the reading of the reflections from the summer institute during which patterns in the participants responses were identified. The data analysis was aimed at answering the research questions and identifying themes, categories, or types (Miles & Huberman, 1994). Successive readings of the data necessitated modification and further development of the coding categories.

Results

Opportunities to Deepen Teacher Mathematical Knowledge and Algebraic Connections

To address research questions, "what changes in teachers' development of the algebraic connections were evident through the activities and professional learning opportunities", and "what essential professional development opportunities and support are necessary for teachers as they transition into teaching through problem solving and making algebraic connections?" we analyzed the reflections from problem solving tasks during the content-focused summer institute and from the Lesson Study.

The analysis of teachers' reflections revealed four main themes: teachers developed a) an awareness of their own metacognitive process during problem solving tasks; b) an appreciation of the need for specialized mathematics knowledge; c) connections to teachers' classroom practices based on one's own reflection from tasks; d) awareness of the affective nature revealed during the learning processes. Below are representative excerpts from the qualitative analysis.

Awareness of Teacher's Own Metacognitive Process During Problem Solving Tasks

The developing awareness of one's own metacognitive process encouraged reflection upon personal learning and problem solving style preferences, identification of common pitfalls and misconceptions that accompanied the problem solving process, and the ability to internally perform task analysis in order to generate multiple problem solving ideas.

> After Dr. S. shared how Gauss' thinking connected to this problem, it seems to keep coming up in other problems we have solved. It all started with the handshake problem and then it appeared again in the toothpick problem, the fruit stack problem, and the penny jar problem.

> While I could identify and extend a triangular number pattern, the importance of the pattern was not something I thought was significant. I don't ever recall noticing this triangular number pattern, and it seems to keep coming up in numerous problems. 1, 3, 6, 10…now, I keep seeing this pattern everywhere. – Elementary math specialist

Appreciation of the Need for Specialized Mathematics Knowledge

Participants noted that using multiple strategies and representations to solve rich questions that required deeper mathematical thinking increased their understanding of algebra concepts. Teacher learners immersed in a content-focused institute and asked to explore novel approaches and unfamiliar tools and technology experienced an expanded appreciation of algebraic connections and representational fluency.

> I noticed that when he explained his strategy to our other partners, his visual really seemed to be clearer than my abstract expression. That was very powerful for me because I need to always keep in mind as a teacher that all of my students learn in different ways and are all at very different levels. While some of my students may be ready for the algebraic expression, there are so many important benefits that can be gathered from the pictorial/graphical representations as well. -7th grade teacher

Making Connections to Teachers' Classroom Practices Based on One's Own Reflection From Tasks

Throughout the institute, participants grappled with problems as students themselves and saw the value of rich problems that encourage multiple approaches and rich discussion. They personally experienced the connections that exist algebraically within and between the mathematical strands of number, geometry, measurement, and statistics. Scaffolding opportunities, differentiation potential and readiness assessment were all named as benefits of this type of learning environment. However, many did voice concern over barriers within their schools that could impede implementing these newly learned and appreciated reform practices.

> Obviously I have thought about how I might use this problem in my own classroom this year. I am excited to see what algebra I can bring out for my students and how I can modify a lesson focused on inequalities to a new lesson focused on algebraic expressions.
>
> As I think through how I will adjust and focus this lesson for my sixth grade students I am oriented on two main factors. First, I need to consider multiple representations and access points in my classroom. I need students to feel comfortable seeing problems in multiple representations and then get them comfortable trying to use these approaches (concrete, pictorial, graph, symbolic, verbal) to solve problems. I also must consider how I present a problem—how can I make sure all of my students have an access point to solving a problem?- 6th grade teacher

Awareness of the Affective Nature Revealed During the Learning Processes

The teacher learners voiced both struggles and satisfaction during the problem solving processes. They appreciated the collaboration and support from colleagues and emphasized the importance of mathematics communication to building mathematical ideas.

> The next two classes were painful to say the least, by Thursday I was ready to tell my partner I couldn't do this. She talked to me all the way to class but I was not really convinced. Then like a flash, all start falling into place. As I pass the pages, I look at the pizza problem. That was the one that gave me confidence. I saw the connection with the handshake problem. I thought, what was different this time. As I was thinking about that, Habits of Mind came to my thoughts. I realized that I was beginning to use them in my problem solving. That is something I want to impart in my students! – 4th grade teacher

Catalysts for Change: Essential Opportunities for Teachers to Develop Algebraic Connections

As we coded teachers' reflections from the designed project activities, key events stood out as being pivotal points in eliciting teachers to rethink their practices. We identified these key activities as the Catalysts for Change in our teachers because these activities seemed to be the events in which teachers realized they needed to change their way of thinking about their instructional practices for mathematics teaching and learning.

Key Activity 1: Teachers Immerse in Rich Problems with Algebraic Connections

It was important for teachers to grapple with the problems and experience disequilibrium. This opportunity allowed for teachers to make connections to the fundamental algebra and increase their understanding of the topic. It was a "relearning" process for many who were making sense of the algebra that they had learned procedurally; void of context or real life applications. These connections were made by both experienced and novice teachers. We coded this as '*making connections and see algebra in a new way'.* An experienced eighth grade teacher who currently taught Algebra was able to see the content in a new way. One excerpt from her reflection said,

> Just as I needed to make connections between the context, my rule, and why it worked, students of all ages need these same opportunities. Previously when teaching students about triangular numbers, I focused on the number pattern and the geometric pattern. It was solely identifying what is happening by doing and undoing and extending the pattern, perhaps even getting to build a rule. What was totally missing from my instruction? Problems in which triangular number patterns actually appeared! Pretty big I think. Just as my understanding of triangular numbers and algebra deepened, students will receive the same benefit by having opportunities to take their understanding of patterns and apply it to more complex situations. *-8th grade teacher*

We also noticed that these activities elicited teachers developing representational fluency and valuing the use of multiple representations. A novice 5th grade teacher excerpt was coded *'developing representational fluency'* because she expressed using multiple representations as she solved and made sense of the problem and also made connections to how her students might gain access to the problem through a visual approach.

> Reflecting back on how I solved the problem I notice that I used many different representations to help me solve the problem. First I drew a picture, then I used a table, and last I used symbols. This idea of multiple representations was accented in class and made me process how students might need different entry points to be able to engage in this problem. It made me think about how to set up a problem and get students started on a problem. The visual used in class was extremely helpful for me, even though I could access the problem in other ways. It reinforced what I saw was going on in the problem, but had I been a child that could not see what was going on, it would have given me an opportunity to engage in the problem (*5th grade math and science teacher).*

Key Activity 2: Opportunities for 'Teacher Math Talk' on Algebra and Vertical Articulation

The importance of collaboration and vertical articulation came to the forefront as teachers discussed problems with their colleagues and talked about the grade level mathematics expectations. One teachers commented how her team members helped her build on her existing ideas about algebra.

> As we have worked through problems this week, I have been very fortunate to sit with colleagues who teach at a range of grade levels. Our table actually represented grades 3-6. As

> we shared our thinking and problem solving strategies, I learned to see the big, intricate picture from them. There were times when it seemed that they gained a lens by hearing about my analysis of a table, my exploring with manipulatives, or through my illustrations. *-3rd grade teacher*

This was a great connection to what research has noted about how students learn from class discussion (Hufferd-Ackles, Fuson, & Sherin, 2004). We observed teachers learning from the mathematical discussions, questioning, explaining mathematical thinking, and debating mathematical ideas. This critical activity also elicited teachers' responses to recognizing the importance of breaking down the essential mathematical learning, identifying the common student misconceptions and scaffolding and differentiating for diverse learners.

> I feel most prepared to teach my students to use multiple representations, to notice patterns, and build rules. I think it was most helpful to solve problems collaboratively in the summer class and to share our solutions. It was interesting to see the various ways my classmates solved the problems. *-Special educator who teaches in an inclusive classroom*

In many ways, this opportunity allowed teachers to simulate the math talk that they would conduct in their own classroom. Having a chance to discuss potential misconception, analyze sophistication of solution strategies, and ways to create parallel tasks for differentiation allowed teachers to have a natural conversation of progression of mathematical ideas and vertical articulation.

Discussion

At the end of the course, participants reflected on how their participation in the yearlong professional development session had impacted their ideas of algebra in the early grades. The most common themes were that they "relearned" the math by being in the "shoes of the student" and having to solve challenging problems while breaking down the important mathematics helped them see the early building blocks for creating algebraic connections. These experiences not only increased their confidence in the teaching and learning of mathematics but also helped the participants to develop a productive disposition towards mathematics.

This study revealed that engaging teachers in challenging activities that created some sense of disequilibrium led teachers to reflect on their knowledge, their problem solving process, and their instructional practice. Participants' positive experiences during the learning process helped develop a more productive disposition towards teaching algebraic reasoning through problem solving and through multiple representations, and value collaborating with other mathematics educators in translating their learning into practice. In addition, the study demonstrated the effectiveness of the choice of rich problems that helped us to study teacher's developing knowledge and that also provided the teachers with useful examples for algebraic instruction and student learning assessment. It is the authors' hope that the results of this study contribute to the growing body of knowledge documenting how professional development serves as a catalyst for change in teachers as they take time to reflect and relearn specialized knowledge for teaching algebra in the early to middle grades.

DIFFERENTIATING ALGEBRAIC EQUIVALENCES IN CLASSROOM NETWORKS

Scot M. Sutherland
University of California, Davis
ssutherland@ucdavis.edu

Tobin F. White
University of California, Davis
twhite@ucdavis.edu

Equivalence in algebra has different meanings in different contexts and a sophisticated understanding of equivalence is required to solve increasingly complex problems. This study builds upon previous design research studies that illuminate how mathematical constructs can be mapped to social relationships to support mathematical meaning making. We follow how one student's conceptions of equivalence changed as he worked with three different partners on four algebra learning activities in two novel classroom network based learning. We illustrate how differing affordances in the learning environment lead to different forms of mediation when disagreements accompany differing mathematical conceptions in a classroom network environment.

Introduction

Algebra gains much of its power from the flexible use of equivalence (Gattegno, 1974), and students often find it difficult to negotiate different kinds of equivalence in different contexts (Linchevski & Herscovics, 1996). Peer discussions mediated by technology and instruction support convergence of mathematical meaning (Moschkovich, 1996) and the development of more sophisticated conceptions of equivalence. Our own ongoing design based research project aims to foster mathematical conversations and interactions in pairs and small groups using handheld network technology (White, 2006; White, Sutherland, & Lai, 2010). Broadly, and building on prior research involving classroom network systems (Stroup, Ares, & Hurford, 2005), our design approach involves mapping social relationships between students to mathematical constructs embedded in technology to create opportunities for students and the teacher to interact in ways that make mathematical relationships explicit.

The present study focused on investigating students' developing ideas about equivalence in the context of two different learning activity designs, each of which featured an equivalence engine intended to support students' joint engagement with algebraic expressions as they constructed polynomials and transformed equations. We follow one student as he worked with three different partners over four different sessions using these two different activity designs, and examine instances in which disagreement between partners occurred when students differed in their conceptions of equivalence in a particular context. Disagreements in discourse signal a dialogical conflict of meaning (Bakhtin & Holquist, 1981) that both emerges from and is mediated by agents and tools in a particular context (Kozulin, 2003). The episodes presented here are the result of an ongoing exploration of how student understanding of equivalence in different contexts emerges from and is mediated by resources, tools, teachers and other students. In particular we highlight the way disagreements between students accompany differing mathematical conceptions of equivalence and how different affordances of two activity designs influence mediation of these disagreements in a classroom network learning environment (Ares, Stroup, & Schademan, 2009; Stroup, et al., 2005).

Equivalence in Algebra

Students initially conceive of the equal sign as a signal that a solution will follow. This operational understanding of equivalence gradually gives way to an understanding equivalence as a comparison of equal values (Kieran, 1981; Rittle-Johnson, Mathews, Taylor, & McEldoon, 2010; Sfard & Linchevski, 1994). A sophisticated understanding of equivalence becomes increasingly important as problems become more complex (Knuth, Stephens, McNeil, & Alibali, 2006). Operational conceptions of equivalence in certain contexts can persist into college even for students who do well on standardized tests (McNeil & Alibali, 2005). Below, we introduce two different classroom network-based collaborative learning activity designs intended to address these challenges by supporting an instructional sequence in which students jointly explore and negotiate meaning of algebraic equivalence relations in different settings.

Two Learning Environment Designs for Exploring Equivalence

The learning activities in this study featured two different classroom network designs: *Terms and Operations*, focused on students' collaborative efforts to construct polynomial expressions, and *Two-Sides*, centered on pairs' joint transformations of shared equations. Both learning environments were created with the NetLogo modeling platform (Wilensky, 1999) and HubNet architecture (Wilensky & Stroup, 1999) connected to a class set of TI-83 graphing calculators that function as handheld devices on the network.

Equivalence of Expressions in Terms and Operations

The *Terms and Operations* activity design allows the teacher to populate a field with floating monomial terms (Figure 1). Pairs of students each construct a collective expression by alternately adding, subtracting, multiplying or dividing a term captured from the field. To complete each transaction the student must enter the result of the operation as an equivalent expression.

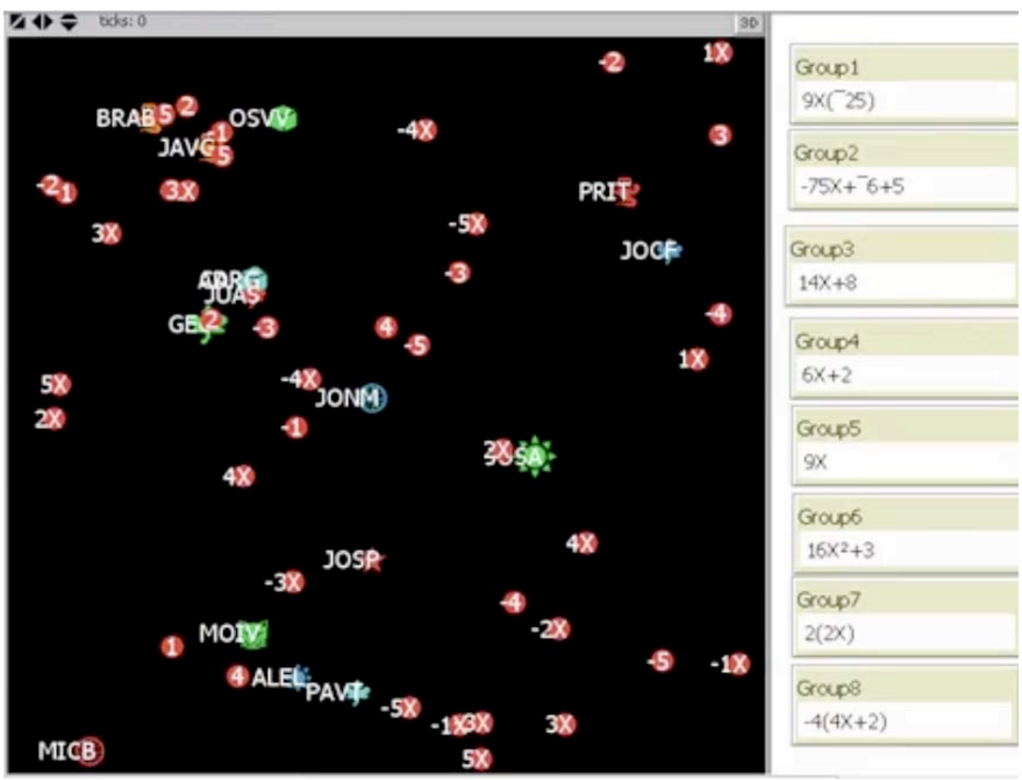

Figure 1. ***Terms and Operations*** **shared display with floating terms and collective expressions.**

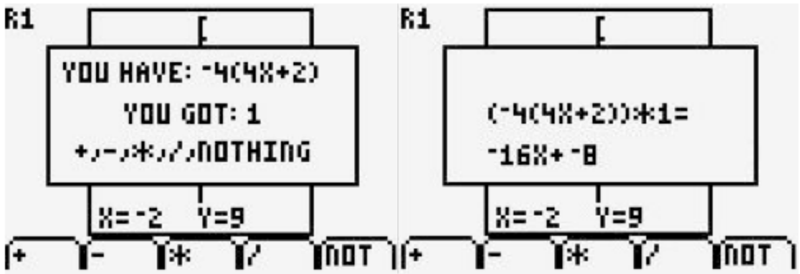

Figures 2a and b. Student calculator screens featuring a) captured term and operation choices and b) a collective expression under the chosen term and operation and an equivalent student entry.

The system updates the collective expression only if the result of the operation and the expression entered by the student are equivalent. When the expression entered by the student is not equivalent the collective expression remains unchanged. The *Terms and Operations* design verifies equivalence of expressions by providing feedback in the form of updates to the collective object.

Equivalence of Equations in Two-Sides

The *Two-Sides* activity design builds on previous designs by verifying both equivalence in the context of expressions and equivalence in the context of equations. Each member of the student pair is assigned to either the left or right side of an algebraic equation. To create a new equation each student in the pair must enter a valid algebraic expression. The networked relationship between the two student' calculators in the *Two-Sides* environment acts as an equal sign for the equation they share. Each member of the pair can transform her own side of the equation by entering any equivalent expression. The system updates the equation to reflect the transformation only if the new expression is equivalent to the original expression. When the pair wants to transform the entire equation they must coordinate the transaction by pressing the operate button and entering equivalent operations on both sides.

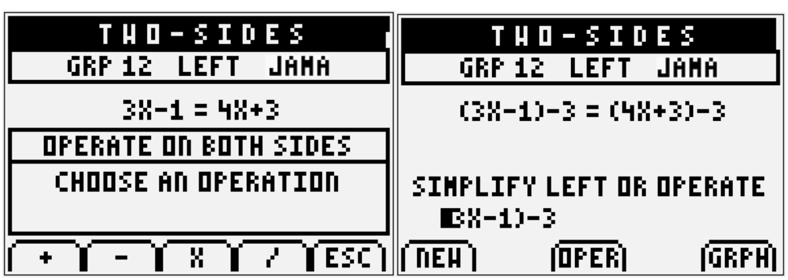

Figure 3a and b. ***Two-Sides*** **left student calculator screens showing the coordination of operating on both sides of an equation.**

The system updates the equation only if the operations by both students are equivalent. *Two-Sides* maps the algebraic equation to the partner relationship by acting as the equal sign between them, making it necessary for the pair to reach agreement when transforming the equation.

Method

The data considered in this study were drawn from a yearlong project in which ninth grade students at a non-traditional urban charter school organized around project-based learning participated in classroom network activities for one hour-long session each week as a supplement to regular pre-algebra and algebra 1 instruction. On the basis of informed consent two to three student pairs were selected as focus groups and videotaped for all activities. All screen states of the public computer display were recorded as a video file for each class session, and an additional camera with a wide zoom setting captured this projected display along with the whiteboard at the front of the room, as well as whole-class discussions and other teacher moves. Server logs recorded all activities on both the shared displays and the student calculators. Episodes involving disagreements between partners were flagged and coded by topic of the disagreement. Disagreements that did not involve a conflict of mathematical meaning were dropped. Conflicts over the meaning of equivalence in a particular context were selected, annotated and transcribed. The present study follows one student, Jamal, as he worked with three different partners over four different class sessions—two each in the *Terms and Operations* and *Two-Sides* activity designs. Disagreements that signaled dialogical conflict of the meaning of equivalence between Jamal and his partner during the four sessions were considered for analysis. The segments presented here were selected to illustrate how the activity design illuminated and mediated student conceptualization of algebraic equivalences in different contexts.

Analysis

Episode 1: Differentiation of X term and Constant Term Equivalence

Jamal and his partner (Sara) had been introduced to *Terms and Operations* in a previous session but had worked in different pairs. In this session the teacher instructed students to construct an expression using the four basic operations (add, subtract, multiply and divide), recording each step on paper and simplifying along the way. They had constructed a -20 using the sequence -1 * 5 * 4 when Jamal captured a -5X and subtracted it from the -20. The following disagreement occurred over the simplification of -20 - -5X:

1. Sara: That's going to be -25X
2. Jamal: Hold up. It's -20…
3. Sara: Yes it is…
4. Jamal: [Thinking aloud] -20 + 5X.
5. Sara: Hold up, hold up… -100X … -100X
6. Jamal: Really? What?
7. Sara: I'm subtracting…
8. Jamal: A hundred… How did you get a hundred?
9. Sara: No wait wait (he he)
10. Jamal: It's -20 + 5X
11. Sara It's a positive… wait it's a negative [as Jamal enters -20 + 5X into the calculator]
12. Jamal: Got it! It's -20 + 5X [both looking at the shared classroom display]
13. Sara So what's the answer?
14. Jamal: -20 + 5X
15. Sara: Huh?

The disagreement occurred when Sara attempted to construct a single equivalent term for an expression that included a linear term and a constant term. Note that Sara took into account all three negative signs when constructing a negative term (line 1). In contrast Jamal assigned the first negative symbol to the constant term and correctly interpreted the double negative on the X term (lines 2, 4, 10-12). Jamal's confidence in his version of the expression exposed Sara's uncertainty as she abandoned -25X in favor of -100X (line 5). Sara expected an answer in the form of a single term and expressed surprise (line 15) when the system verified the equivalence of Jamal's binomial expression. The *Terms and Operations* design exposed the differing conceptions of equivalence in the two students and provided important mediation by confirming the equivalence of Jamal's suggestion.

Episode 2: Ascribing the Rules for Equivalence in an Equation to an Expression

Jamal joined another partner (Irene) for the next *Terms and Operations* session. The teacher explained the distributive property and instructed the students to construct any expression equivalent to 2(X + 3) + 4. The following disagreement between the pair and the teacher occurred after Jamal and Irene had successfully constructed 2X + 10. They asked the teacher if they could divide by 2 to simplify the expression to get X = 5:

16.	Teacher:	X = 5. Okay. Where is the equal sign in here right now? [pointing to 2X + 10]
17.	Jamal:	Or, X + 5.
18.	Teacher:	X + 5. So you want to divide this thing by 2… [writes (2X + 10)/2] You're dividing this whole expression by 2. On the calculator you would write it out like this. Yes, Jamal you are right if I did divide this by two 2X/2 = X and 10/2 I = 5. So this is what (2X + 10)/2 would equal.
19.	Irene:	It's 5X.
20.	Jamal:	No 5.
21.	Teacher:	X + 5. No?
22.	Jamal:	[Looks stumped]
23.	Teacher:	Okay what were you saying Jamal.
24.	Jamal:	[Shakes head] Nothing.
25.	Teacher	What are you thinking Irene?
26.	Irene:	[giggles]
27.	Teacher:	Not sure? Here's the thing: is X + 5 = 2(X + 3) + 4? [Points to board]
28.	Jamal:	No.
29.	Teacher:	Why not?
30.	Jamal:	[Tentatively] Well, it is. It's confusing me.
31.	Teacher:	Here's one thing we could do. Let's say we knew what X was. Let's say X = 1. What would X + 5 be equal to if X = 1.
32.	Jamal:	[writing on paper] 6 and the other one would be 13… or no it would be 12.
33.	Teacher:	How do you make a 6 equal to a 12?

Implicit in the instructions for this task was the notion that 2(X + 3) + 4 would equal some equivalent expression. Jamal and Irene successfully constructed 2X + 10 which does equal 2(X + 3) + 4, but the *Terms and Operations* collective display showed only 2X + 10. *Terms and Operations* verifies equivalence of expressions but does not check for equivalence of equations, so Jamal attempted to verify the next move by asking the teacher if they could divide 2X + 10 by 2 to make X = 5. Clearly Jamal and Irene drew on prior experience of solving equations to make this suggestion, attempting to apply rules for equivalence in the context of equations to an expression. Irene combined the constant term and X term by suggesting that 5X might be a better candidate. The teacher mediated the disagreement by suggesting that a 1 be substituted for X. Jamal did the calculations and realized that 6 ≠ 12. The learning environment did illuminate the misconception of equivalence proposed by Jamal and Irene, but the teacher provided mediation because *Terms and Operations* does not address equations.

Episode 3: Equivalence in Equations versus Expressions Revisited

The teacher began the session by explaining that to solve an equation the X must be isolated on one side through the use of equivalent operations to both sides. Providing a list of equations to solve, the teacher introduced the *Two-Sides* activity design for the first time and challenged the students to solve as many of the equations as they could using the calculators. Jamal and his partner (Megan) had just restarted the program after a technical glitch and found that they had reversed roles. A disagreement occurred over what they should do to each side of 3X + 4 = X - 6 to move toward a solution.

34. Megan: Yes. Minus X. [Selects operate and chooses subtract X]
35. Jamal: I have to, like, subtract 4. Huh. [Selects operate, chooses subtract and types a 4]
36. Megan: No. Minus X. [Almost grabbing the calculator so Jamal will subtract X instead of 4.]
37. Jamal: Yeah.
38. Megan: No. We're supposed to do the same thing. You have to do the same thing so minus X.
39. Jamal: Minus…X. No… Dammit! [Types as he talks and presses enter]
40. Megan: You got it… There you go.
41. Jamal: Oh, dooney! [surprised and puzzled]

Both Jamal and Megan attempt to eliminate a term from their own side of the equation, but Megan understands the additional requirement that equivalent operations must be performed. Jamal expressed puzzled surprise (line 41) when the system validated subtracting X from both sides. The disagreement between Jamal and Megan corresponded to differing conceptions of equivalence in the context of equations. The *Two-Sides* system mediated the disagreement in a way that *Terms and Operations* did not by checking for equivalence of both equations and expressions.

Episode 4: Equivalence in Equations versus Expressions Resolved

Jamal rejoined Megan in a later session in which the students were challenged to enter any equation that contained at least one X term and a constant term on the same side. Megan entered 2X – 3 and Jamal entered 9 to form 2X – 3 = 9. The disagreement occurred over the first step in solving the equation.

42. Jamal: 2X – 3 = 9
43. Megan: …X – 3 = what?
44. Jamal: 9. I'm supposed to put the right 9. You're suppose to put 2X – 3… Then you subtract 3 and I add 3.
45. Megan: No. We both add it.
46. Jamal: Both add or both subtract?
47. Megan: No. We both add it.
48. Jamal: [Jamal watches the screen intently as the system updates] Oh, yah [unintelligible.]
49. Megan: Ok. Now simplify
50. Jamal: So 9 + 3 is 12. [They arrive at 2X = 12]

Jamal continued to struggle with the requirement that the same operation must be performed on both sides of an equation (line 44). Even after agreeing that the same operation must be performed on both sides Jamal struggled to anticipate the consequences on the equation as a whole (line 46). Jamal's intense concentration on the shared display indicated that the result meant something important to him. This conjecture was further supported by his affirmative response to the result (line 48), and his immediate simplification of his own expression (line 50).

The teacher began to explain to the class how the graph on the *Two-Sides* shared display related to the equation Megan and Jamal had made. Jamal decided to test his newfound understanding despite the fact that the teacher was using the graph of their equation as an example.

51.	Jamal:	[While Teacher talks Jamal initiates a divide by 2 and taps Megan to show her what he's doing.]
52.	Megan:	[Megan also divides by 2 and the shared display updates to X = 6. Changing the graph the teacher is using as an illustration]

Jamal recruited Megan to divide by 2 on both sides. The teacher was unaware of the update, which caused a few moments of levity in the class. Here the *Two-Sides* design was able to verify the equivalence of Jamal's proposal in the context of equations in a way that *Terms and Operations* could not, supporting Jamal's prediction that dividing both sides by 2 would produce the desired result. Unlike the prior instance during this episode (lines 45-47), Megan readily agrees because their conceptions of equivalence for this operation were the same. It is possible that Jamal used a guess and check strategy to arrive at the correct solution for the equation, but he was required to divide both sides by two to verify this. *Two-Sides* and Jamal's partner Megan provided mediation in the form of positive feedback.

Discussion

The *Terms and Operations* and *Two-Sides* activity designs enabled Jamal and his partners to jointly construct expressions and equations. In Episode 1 the *Terms and Operations* design mediated the disagreement between Jamal and Sara over the equivalence of expressions. However, when Irene and Jamal ascribed the rules of equivalence for equations to an expression in Episode 2, mediation shifted to the teacher because *Terms and Operations* did not verify equivalence for equations. The *Two-Sides* design tested equivalence for both expressions and equations providing mediation for Episodes 3 and 4. The different affordances of the two tools led to different forms of mediation of the disagreements between Jamal and his partners.

The design of the learning environment mapped the social relationships to the mathematical construct. Each move by the pair necessitated an agreement on a conception of equivalence in a particular context. Disagreement created the need to test one competing conception using the tools in the learning environment. When the *Terms and Operations* could not verify equivalence of equations the students turned to the teacher to resolve the disagreement.

The contrast in the mediation of equivalence between the two designs shifted mediation away from the teacher in certain contexts and toward the teacher in others. Collaboration supported by technology gave way to more teacher directed forms of instruction when the technology could not mediate disagreements. Student conceptions of equivalence were mediated, but the form of mediation differed depending upon the affordances of the learning environment.

Jamal shows increased sophistication in his understanding of equivalence over the course of the four sessions. He could negotiate equivalence of expressions (Episode 1), but ascribed rules for equivalence of equations to expressions (Episode 2). Working in the in the *Two-Sides* learning environment he began to differentiate between equations and expressions (Episodes 3 and 4). The technology both informed and supported different forms of instructional practice and promoted new kinds of classroom interactions that led to learning for Jamal.

This study took place in a non-traditional charter school with mix of both algebra 1 and pre-algebra students. Students volunteered to participate in the study on a once per week basis. The influence of mediation cannot be generalized beyond this study, and the influence of technology should be taken as an example of how pedagogical possibilities emerge from designs like these. Further research will be required to explore these possibilities in the context of classroom network learning environments.

VALIDATING TWO PROBLEM-SOLVING INSTRUMENTS FOR USE WITH SIXTH-GRADE STUDENTS

Jonathan D. Bostic
Bowling Green State University
bosticj@bgsu.edu

Stephen J. Pape
University of Florida
sjpape@coe.ufl.edu

Tim Jacobbe
University of Florida
jacobbe@coe.ufl.edu

A validation study was conducted to explore properties of two problem-solving measures. One hundred sixty-nine students responded to two problem-solving instruments that were adapted from prior research (Verschaffel et al., 1999). Students completed the instruments during their mathematics class with one week between test administrations. There was sufficient evidence of good fit using a one-factor model for both measures. Item difficulty and discrimination were examined using Item Response Theory.

Introduction

Mathematically proficient students at any age make sense of word problems, evaluate their progress while problem solving, and interpret their solution (Chief of Council State School Officers (CCSSO), 2010; Kilpatrick, Swafford, & Findell, 2001). Unfortunately, data suggest that adolescents in the U.S. have difficulty solving complex word problems (Gonzales, Williams, Jocelyn, Roey, Kastberg, & Brenwald, 2009). With many states adopting standards that reflect the Standards for Mathematical Practice (CCSSO, 2010), assessments that capture students' problem-solving performance and align with these new standards are necessary. Instruments drawing on Item Response Theory (IRT) concepts and procedures are likely to produce more accurate estimates of problem-solvers' abilities than Classical Testing Theory (CTT) approaches (de Ayala, 2009; Embretson & Reise, 2000). Problem solving is briefly discussed followed by the benefits of IRT and a brief description of key terms typically used in IRT. The goal for this study was to revise and validate problem-solving tests from Verschaffel et al. (1999) using IRT and factor analysis.

Literature Review

Problem Solving

"A problem occurs when a problem solver has a goal but lacks an obvious way of achieving the goal" (Mayer & Wittrock, 2006, p. 288). Verschaffel et al. (1999) suggest that word problems should be open, realistic, and complex. Open problems provide learners multiple entry points and can be solved in different ways. A realistic task is developmentally appropriate and draws on a problem solver's prior knowledge. A complex problem requires an individual to employ sustained reasoning to solve it. More accurate and appropriate evaluations of students' problem-solving ability may be possible with problems drawing on these components. Problem solving goes beyond procedural thinking typically associated with solving exercises (Polya 1945/2004; Mayer & Wittrock, 2006). Problem solving

> usually involves several iterative cycles of expressing, testing and revising mathematical interpretations – and of sorting out, integrating, modifying, revising, or refining clusters of mathematical concepts from various topics within and beyond mathematics. (Lesh & Zawojewski, 2007, p. 782)

Exploring the ways students solve word problems in addition to their performance adds to the literature on students' problem solving and strategy use.

Prior research provides a foundation for creating new instruments with tasks that are open, realistic, and complex. Verschaffel and his research team (1999) explored the impact of teaching mathematics through problem-solving contexts on fifth-grade students' problem-solving performance. Four classes received 20 lessons meant to foster effective problem solving while seven classes continued with their normal instruction. A total of 232 participants completed both a pretest and posttest. Instruments were composed of ten open, realistic, and complex word problems. Each item on the pretest had a similar task on the posttest. Reliability for the tests was .56 and .75. Items were scored as correct, technical error, or incorrect. Technical errors were characterized as minor arithmetic errors, which were counted as correct responses in terms of students' performance. The tasks' open-ended nature would have supported explorations into students' strategy use; however, these analyses were not conducted. Results from the posttest indicate that on average, students from the intervention group had better problem-solving performance than those in the comparison group on the posttest, $p < .05$. Verschaffel et al. (1999) note a lack of problem-solving instruments using open, realistic, and complex tasks suitable for adolescents. Measures with well-documented and appropriate psychometric qualities could not be borrowed hence tests were created to suit the aim and scope of the study. Further research is necessary to make a version of the instruments for English-speaking students but also, the items' contexts may need updating. A second limitation Verschaffel et al. (1999) discuss was the lack of validity-related evidence associated with their instruments. The large number of participants would have afforded an investigation to gather statistical validity using IRT (de Ayala, 2009; Embretson & Reise, 2000).

Item Response Theory

IRT has four critical assumptions, (1) ability is a unidimensional trait, (2) the items are locally independent, (3) the probability of answering items increases as ability increases, and (4) item parameters are independent of respondents' abilities (de Ayala, 2009; Embretson & Reise, 2000). Results from IRT methods produce trait-level estimates of a person's abilities that depend on the individual's responses and the item properties (Embretson & Reise, 2000). Ability estimates are often more precise than CTT results and require fewer items (de Ayala, 2009). Each individual has a standard error estimate instead of assuming one for all respondents (Embretson & Reise, 2000). Respondents' scores can be linked when they take tests that measure the same trait; CTT requires strictly parallel tests (i.e., equal means, variances, and covariances). Finally, results from tests created with IRT procedures can be compared with results from different populations. Advancements in IRT methodologies facilitate updating and improving older problem-solving instruments that relied on CTT. By reexamining tests from earlier research, it may be possible to better estimate a learner's problem-solving ability and facilitate enhanced contexts that support problem solving.

The simplest IRT model is the Rasch model, which suggests that the odds of an examinee answering an item is modeled by the ratio of an examinee's ability and an item's difficulty (de Ayala, 2009; Embretson & Reise, 2000). Item difficulty characterizes the ability needed to have a 50% likelihood to give a correct response is 0.5 (de Ayala, 2009). Generally, an item difficulty below 0 indicates an easier problem whereas greater than 0 characterizes a harder item (de Ayala, 2009). Problem-solving tasks tend to be somewhat more difficult than standard mathematical exercises therefore larger item difficulties are expected. A useful trait of the Rasch model is the Sufficiency property, which indicates that respondents can be rank ordered by their total score. The second property of all IRT models is item discrimination, which characterizes the degree an item can distinguish respondents of differing abilities. The Rasch model constrains item discrimination to a specific value (e.g., 1) or it can vary for the measure. The 2-PL model allows item discrimination to vary for each task but participants cannot be rank ordered.

Method

Participants

All sixth-grade students in ten classes of two sixth-grade teachers from a school in Florida were approached for their consent, 169 students agreed to participate. Approximately 33% of students at the school are eligible for free-or-reduced-lunch (Florida Department of Education (FLDOE), 2010). Sixty-nine percent of students at the school are white, 12% are African-American, 11% characterize themselves as Hispanic, 5% are multiracial, and 3% are of an Asian ethnicity (FLDOE, 2010).

Instrumentation

The problem-solving instruments used by Verschaffel et al. (1999) were translated into English by an individual who previously taught Dutch at the university level. Items consisting of only one sentence were not revised because they were significantly shorter than most tasks. One item-pair relied on pictures and was not selected because the item format was unique from all other tasks. After examining the items, a total of eight item pairs were selected for translation and revision. The problems were revised to update contexts, to reflect U.S. students' experiences, and to clarify the language. For instance, an updated task described food options available in a U.S. school cafeteria (i.e., sandwich, pizza, and hamburger) rather than lunch choices typical of school cafeterias in the Netherlands. The first and second tests are located in Appendix A and B, respectively. When a near-exact translation of an instrument is used, a back-translation may be necessary; however, the contexts of the problems changed dramatically thus a reverse translation was unnecessary.

Two mathematics educators reviewed the tasks for open-ness, relevance to sixth-grade students in the U.S, and complexity. The tests were also evaluated by a fifth-grade mathematics teacher for these same characteristics as well as to verify that the items were realistic for children living in the U.S. and could be solved in multiple ways by students entering sixth-grade. The teacher indicated that the items were open, realistic, complex and further indicated that students entering sixth-grade could answer every question.

Data Collection

Measure administration occurred during students' mathematics class, which lasted 45 minutes. The measures were completed one week apart. Most students completed the first test over one-and-a-half mathematics periods whereas they finished the second test during one mathematics period. The measures were distributed to the students, the directions were read out loud, and students who asked for assistance were told to reread the problem and answer the question to the best of their abilities. Students did not have access to calculators during testing.

Analysis

Initially tests were scored using Verschaffel et al.'s (1999) scheme including incorrect (0 points), incorrect because of an arithmetic error (1 point), and correct (2 points). There were very few occasions of arithmetic errors (i.e., less than two percent of all responses) and a dichotomous

IRT model effectively suited the tests without sacrificing loss of information hence the scoring scheme was simplified to incorrect and correct (i.e., zero and one, respectively). Responses with arithmetic errors were collapsed into the correct category. A sample consisting of 20% of tests was randomly selected, two coders scored these tests independently and interrater agreement (IRA) using r_{wg} (James, Demaree, & Wolf, 1984) was calculated. IRA is more appropriate than interrater reliability because IRA provides evidence that ratings from the two coders would be identical for all other tests from that sample (LeBreton & Senter, 2008). IRA for both test administrations was within an acceptable range (r_{wg} = .99) (LeBreton & Senter, 2008).

Structural equation modeling procedures were employed to examine the fit of the tests with a single proposed construct: problem-solving ability. IRT analyses were conducted to determine item difficulty and item discrimination. Reliability of each measure was calculated using Cronbach's alpha and Pearson's *r* characterized alternate forms reliability. De Ayala (2009) stresses that a calibration sample with a few hundred respondents "should not be interpreted as a minimum, but rather as a desirable target" (p. 43) and a smaller sample may suffice to estimate item parameters. M-PLUS and R facilitated the model fit and IRT analyses, respectively.

Results

Test and Item Characteristics

The test of model fit for the one-factor solution for the first test was not significant $\chi^2(20) = 20.08$, p = .45 and Root Mean Square Error of Approximation (RMSEA) indicated excellent fit, *RMSEA* = .005. The Confirmatory Factor Index (CFI) and Tucker-Lewis Index (TLI) were both 0.99. Similarly, the test of model fit for the one-factor solution for the second test was not significant $\chi^2(20) = 21.42$, p = .37, *RMSEA* = .021. CFI and TLI for the second measure were 0.99. Root Mean Square Error of Approximation values less than or equal to .06 indicate close fit (Bryant & Yarnold, 1995/2005). CFI and TLI values greater than .90 provide evidence of good fit (Ullman & Bentler, 2009).

Three dichotomous IRT models were explored: Rasch with discrimination constrained to one, Rasch with unconstrained discrimination, and the 2-PL model. A 3-PL model was not considered because the sample was not large enough and guessing the answer on a constructed-response item is unlikely. Data were subjected to analyses and then each model was compared using ANOVA to support the decision for the most appropriate model. Statistical comparisons are helpful, but simplicity of models should take precedence when there appears to be little information gained from using a more complex model (de Ayala, 2009). The Rasch model with unconstrained discrimination showed a slight improvement over the Rasch model with constrained discrimination for the first test, $F(1)$=3.09, p = .08, and there was no statistical improvement with the 2-PL model, $F(7)$= 10, p = .19. For the second test, the Rasch model with unconstrained discrimination was an improvement over the Rasch model with constrained discrimination, $F(1)$=4.62, p = .03, and the 2-PL model was statistically better than the unconstrained Rasch model, $F(7)$=15.92, p =.03. The first test fit the constrained Rasch model fit best whereas the 2-PL model was selected for the second test. Tables 1 and 2 provide the item information for each instrument.

Table 1. Item information for first test

Test Parameters	Item							
	Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8
Difficulty	-0.49	2.82	2.47	1.74	0.99	1.65	1.69	1.53

Std. Error	0.17	0.39	0.34	0.25	0.19	0.24	0.24	0.23
Discrimination	1.24	1.24	1.24	1.24	1.24	1.24	1.24	1.24
Std. Error	0.14	0.14	0.14	0.14	0.14	0.14	0.14	0.14

Table 2. Item information for second test

Test Parameters	Item							
	Q1	Q2	Q3	Q4	Q5	Q6	Q7	Q8
Difficulty	-0.38	4.07	3.32	0.99	0.75	1.01	1.31	0.68
Std. Error	0.38	2.13	1.38	0.17	0.19	0.27	0.34	0.13
Discrimination	0.71	1.03	0.79	2.31	1.44	1.1	1.05	2.8
Std. Error	0.25	0.67	0.38	0.71	0.38	0.31	0.31	1.02

These results suggest that overall, the first test had fairly difficult items and it discriminated between participants well. The second test also had a number of difficult items and each item tended to discriminate fairly well. Cronbach's alpha for the first and second test was 0.60 and 0.62 respectively. Approximately 75% of the participants earned two or fewer total points on the first measure and 60% of the participants earned two or fewer points on the second measure. The minimum correlation coefficient to link scores across tests measuring the same latent trait was .60 (Ary et al., 2009). Pearson's correlation indicated the alternate forms reliability was 0.60, sufficient for exploratory studies with new instruments (Ary et al., 2009).

Discussion

These items were reasonably difficult and discriminated fairly well among participants. Most items' difficulty ranged from 0.69 to 1.74, which is within De Ayala's (2009) suggested range from negative one to positive two. This range for the problem-solving measures indicates that a student with above-average ability had a good probability of answering the item correctly. Items with a discrimination parameter value from 0.5 to 2.5 are satisfactory items (De Ayala, 2009); every item was within this range. The lack of negatively discriminating items suggests that students with higher abilities were able to answer more difficult tasks.

These results confirm that sixth-grade students experiencing typical mathematics instruction tend not to perform well on problem-solving tasks. Fifth-grade students' mean score, M=1.6 (Verschaffel et al., 1999) was similar to these sixth-grade students score on the first test. The first test is not necessarily harder than the second test, even though participants' average score was higher. For instance, items one, two, and three are easier items than items four through eight.

Results from this study indicate directions for future research using these instruments. First, items two and three on the measures should not be used in their present form because the item difficulties were exceedingly high. De Ayala (2009) suggests that item difficulties greater than two may not function well with a normal sample thus some items should be revised and reexamined. Second, students tended not to use pictorial strategies, which would have been efficient and effective. Participants might have fared better had they considered pictorial approaches, which would have elucidated the solution to questions two and three rather quickly. Research investigating the degree to which non-symbolic strategies are a part of instruction is necessary. Future studies using these instruments should continue to refine the tasks while maintaining their open, realistic, and complex nature.

Appendix A

1) Ruth is planning to serve ice cream sundaes to guests at her birthday party. She purchased 3 flavors of ice cream: vanilla, chocolate, and strawberry, 2 different sauces: chocolate and caramel, and 4 different toppings: bananas, nuts, sprinkles, and whipped cream. How many different types of sundaes can be made if every guest selects only one ice cream flavor, one type of sauce, and one topping?

2) Jerome needs 1 gallon of paint in order to paint a bedroom ceiling that is shaped like a square and measures 12 feet on each side. How many gallons of paint would he need to paint a living room ceiling that is shaped like a square and each side measures 24 feet?

3) Bill is making a gate for a wooden fence to keep his dogs in his yard. He bought four boards of wood from the home improvement store. Each board measures 10 feet in length. He needs 3 foot 6 inch pieces of wood to build the gate. How many pieces can Bill make from his four boards?

4) A youth group and their adult chaperones want to visit a water park. The admission fees for this water park are listed below:

Children: $6.00 Adults: $10.50

The total cost for all 17 people in the group to enter the park is $129.00. How many children were in this group?

5) A group of 150 tourists were waiting for a shuttle to take them from a parking lot to a theme park's entrance. The only way they could reach the park's entrance was by taking this shuttle. The shuttle can carry 18 tourists at a time. After one hour, everyone in the group of 150 tourists reached the theme park's entrance. What is the fewest number of times that the shuttle picked tourists up from the parking lot?

6) Aunt Marie purchased 80 Silly Bandz for her two nephews Elijah and Jordan. She gave Elijah 10 more Silly Bandz than Jordan. How many Silly Bandz did Elijah and Jordan each receive?

7) A family is planning a camping trip to a national park and receives the following information about the costs per day:

Camping Fee	
Children 12 years and younger	$3.00 per day
All others	$7.00 per day
Parking for trailer	$9.00 per day
Use of common areas	$1.50 per person per day

The family will camp for 10 days and need to park their trailer each day. The family consists of 4 people including a father, mother, 8 year-old child, and a 14 year-old child. Each person will need to use the common areas on a daily basis. How much will they pay for their camping trip?

8) Maria wanted a bicycle so she started saving all of her money. For every $6.00 that Maria saved, her mother gave her $2.00. Maria had $56.00 after three months. How much money did Maria's mother give her?

Appendix B

1) Students at Sandhill Elementary School purchase their lunches from the cafeteria. There are 3 choices for a main dish: hamburger, slice of pizza, or a turkey sandwich, 4 different fruit options: apple, banana, orange, or peach, and 2 drink options: milk or juice. How many different types of lunches can be made if every student selects only one main dish, one piece of fruit, and one drink?

2) It takes Jeff 1 hour to mow a lawn that is shaped like a square and is 200 feet on each side. How many hours would it take him to mow a lawn that is shaped like a square if each side measures 400 feet?

3) Mr. Lee wants to make jump ropes for his students to use on the playground. He purchases four packages of rope from the home improvement store. Each package contains one piece of rope that measures 25 feet. Each jump rope needs to measure 8 feet 6 inches. He can cut the rope but cannot join pieces together. How many jump ropes can Mr. Lee make?

4) A youth group and their chaperones want to visit the Butterfly Rainforest exhibit at the museum. The admission fees for the Butterfly Rainforest exhibit are listed below:

Children: $6.00 Adults: $10.50

The total cost for all 17 people in the group to enter the museum is $129.00. How many adults were in this group?

5) A group of 150 people were waiting for a glass bottom boat to take them on a trip through a nature preserve. The boat can carry 18 people on each trip. After several hours, everyone in the group of 150 people had gone through the nature preserve. What is the fewest number of trips made by the boat?

6) Natasha and Marianne went to a theme park. Together, they spent $80.00. Natasha spent $10.00 more than Marianne. How much money did Natasha and Marianne each spend?

7) A family is planning to leave their pets at Animal Day Care while they are on vacation. They receive the following information about costs per day:

Kennel costs	
Dog	$11.00 per day
Cat	$9.00 per day
Food	$1.50 per animal per day
Walk	$3.00 per dog per day

The family will need to leave their pets at Animal Day Care for 10 days. They have 1 dog and 3 cats. All of the animals need to receive food on a daily basis and the dog must be walked each day. How much will the family pay for their pets' stay at Animal Day Care?

8) Janice went shopping at the grocery store and saw the following special offer. "If you buy 6 oranges, you get 2 free." She purchased her groceries and left the grocery store with 56 oranges. How many oranges did she get for free?

USING AN ASSESSMENT FOR LEARNING FRAMEWORK TO PERFORM A TEXTUAL ANALYSIS

Jonathan Engelman
Western Michigan University
jonathan.a.engelman@wmich.edu

This report describes data from a pilot study conducting a textual analysis of a recently published Algebra 1 curriculum using a conceptual framework developed from Assessment for Learning (AfL) principles. AfL uses assessment results to change instruction in order to increase student learning. The study sought to explore how the first unit of the chosen curriculum conceived of AfL. Results of this analysis indicated that three categories of AfL were found in the curriculum (Goals, Teaching Planning, and Evidence of Learning) while a fourth category was nonexistent (Constructive Feedback).

Introduction

The literature on Assessment for Learning (AfL) and Formative Assessment (FA) is expansive. In the past twenty-five years, multiple reviews of literature have taken place (Black & Wiliam, 1998a; Crooks, 1988; Natriello, 1987; Sadler, 1989; Wiliam, 2007) as well as critiques of this research base (Dunn & Mulvenon, 2009). The field of mathematics education in particular has accepted the results of this AfL research, as can be seen in the Assessment Standards in the National Council of Teachers of Mathematics (NCTM) *Principles and Standards for School Mathematics* (2000) as well as Wiliam's (2007) review in a recent mathematics education research handbook.

In his review of the AfL literature, Wiliam (2007) expands on the research behind five AfL strategies also found elsewhere (Leahy, Lyon, Thompson, & Wiliam, 2005; Wiliam & Thompson, 2007):

1) "Clarifying and sharing learning intentions and criteria for success"
2) "Engineering effective classroom discussions, questions, and learning tasks that elicit evidence of learning"
3) "Providing feedback that moves learning forward"
4) "Activating students as instructional resources for one another"
5) "Activating students as the owners of their own learning" (Wiliam, 2007, p. 1054).

Wiliam and Thompson (2007) connect these five research-based Afl strategies to three questions derived from Ramaprasad (1983): (1) Where is the learner right now? (2) Where is the learner going? and (3) How does the learner get there? This research has been used to help shape professional development (Black, Harrison, Lee, Marshall, & Wiliam, 2003) to elicit more evidence of the positive effects of AfL already reported (Black & Wiliam, 1998b). Research in AfL has not yet included studies examining written mathematics curriculum, nor the connections any AfL in the written curriculum might have with the enacted curriculum.

The *Principles and Standards for School Mathematics* (National Council of Teachers of Mathematics, 2000) incorporates AfL into one of its six principles. The assessment principle suggests that "assessment should enhance student learning" (p. 22) and "assessment is a valuable tool for making instructional decisions" (p. 23). The enhancement of learning espoused by this document closely follows what Black and Wiliam (1998a) reviewed. In terms of decision-making, this assessment principle emulates the three AfL questions mentioned already, especially the final one: how the learner reaches his or her learning goal. As the major standards document distributed nationally, the NCTM shows its support of AfL in the mathematics curriculum across school mathematics.

Harlen and Winter (2004) maintain that there is a need to assess problem solving, communication, and reasoning as part of the mathematics curriculum. The authors also contend that these strands are not readily assessed in normal testing situations. Harlen and Winter promote FA and AfL as being able to help assess aspects of the curriculum that regular testing are unable to assess. As one criterion for effective formative assessment, Shepard (2007) asserts that the formative assessments should be embedded within the written, enacted, and assessed curriculum. This pilot study sought to explore the depth of AfL in the written curriculum, specifically asking the following: What potential assessment for learning design features are contained in one unit of a standards-based curriculum?

Perspectives

The following analytic framework (Figure 1), based in part on the Assessment Reform Group's (2002) 10 Principles of AfL and in part on the previous research already mentioned, was developed by a colleague and I (Bentz & Engelman, 2010). Figure 1 represents half of the full framework. This framework acted as the tool for analyzing the design features of the curriculum studied in this project. In the framework, "curriculum resources" refer to all curriculum resources available to the teacher and the student. Evidence of Learning seeks to answer AfL question 1, Goals help answer AfL question 2, and Constructive Feedback attempts to answer AfL question 3. Teacher Planning is required for all three questions to be answered.

AfL Guiding Principle	Exemplary Practices					
Constructive Feedback	CF 1: Curriculum materials suggests teachers give students descriptive feedback regarding their learning	CF 2: Curriculum materials suggest that feedback should pinpoint student's strengths and how to develop them further	CF 3: Curriculum materials suggest that feedback recognize learner's efforts	CF 4: Curriculum materials suggest that feedback pinpoints student's weaknesses and is clear about how to improve on work	CF 5: Curriculum materials suggest that feedback takes into account what students can effectively manage at one time	CF 6: Curriculum materials suggest that teachers provide descriptive feedback when the students need/ request it
Goals	G 1: Curriculum materials ensure pupils understand the goals of learning	G 2: Curriculum materials suggest that students partner with teachers to set goals	G 3: Curriculum materials provide students with a clear and understandable vision of the learning goals			
Teacher Planning	TP 1: Curriculum materials provides opportunities to obtain and use information about students' progress towards learning goals	TP 2: Curriculum materials ensure teacher plans can be flexible to respond to students' initial and emerging ideas	TP 3: Curriculum materials enhance all learners' opportunities to learn	TP 4: Curriculum materials offer opportunities for all learners to achieve their best		
Evidence of Learning	EL 1: Curriculum materials provide opportunities for teachers formatively interpret and judge for evidence of student learning and improvement	EL 2: Assessments from the curriculum materials provide students with an opportunity to demonstrate acquisition of knowledge through tasks and question	EL 3: Assessments from the curriculum materials provide students with an opportunity to demonstrate acquisition of skills through tasks and questions	EL 4: Assessments from the curriculum materials provide students with an opportunity to demonstrate acquisition of understanding through tasks and questions		

Figure 1: AfL Analytic Framework

Methods

Research Design

To answer the research question, an exploratory study was conducted. Maxwell clarifies that the goal of an exploratory study is to "generate an understanding of the concepts and theories held by the people you are studying" (p. 79). The pilot study in this report seeks to understand a curriculum rather than people or behavior. The main goal is to describe phenomena and document the characteristics of the phenomena, in this case, phenomena in a mathematics curriculum (Johnson, 2001).

In order to answer the pilot study research question, the case study (Yin, 1998) is modified to investigate a single unit of one reform oriented mathematics curriculum. One unit is defined as the case itself. Since case studies require multiple sources of evidence in order to triangulate (Yin, 1998), three different sources of data were chosen from the same curriculum. My goal in applying the AfL analytic framework is to both discover how easily it can be applied to mathematics curricula while at the same time discover the extent to which that curriculum pre-packages assessment for learning strategies.

Sources of Data

The curriculum chosen was the National Science Foundation funded Center for Mathematics Education (CME) Algebra 1 curriculum (Education Development Center, 2009). The author team incorporated Cuoco, Goldenberg, and Mark's (1996) habits of mind for mathematics into a four-course high school mathematics curriculum. These habits of mind closely follow the ideas put forth by the 2000 NCTM Standards. Because these standards include language supporting AfL, this study endeavored to determine the extent to which the CME curriculum contained AfL strategies.

Within the CME Algebra 1 curriculum, three main data sources were used. The first data source analyzed was the Implementing and Teaching Guide (IG). The entire IG was coded first to get a sense of the intent of the authors – the principles of design the curriculum was built around – as well as certain structural components. By coding the IG first, specific aspects of the analytic framework began to be formulated for their use with certain elements of the student textbook and teacher resource materials. This helped code later sources more accurately.

The second data source was the Student Edition (SE) of the textbook. This source was analyzed second to determine what AfL the students would see independent from anything found in the annotations of the Teacher's Edition. The final data source analyzed was the Teacher's Edition (TE). When analyzing this source, information that exactly duplicated information from the student text was not coded. Only the annotations from the peripheral materials in the TE were analyzed.

The chosen unit analyzed in CME Algebra 1 was Chapter 1 (Arithmetic to Algebra). This curriculum has just eight chapters, each about fifteen lessons long. One chapter of this curriculum is considered a unit. This chapter was chosen to see how the first chapter of the first course in the CME high school curriculum began to use AfL strategies from the outset of the entire CME program.

Potential for Assessment for Learning

Throughout the coding process, any elements of the curriculum coded as AfL did not necessarily make those elements AfL in actual classrooms. Rather, these elements have the *potential* to become AfL depending on how they are enacted in the classroom. For instance, the *Check Your Understanding* element is coded as EL 1, EL 4, and TP 1. This means that any *Check Your Understanding* section in the curriculum offers the teacher three AfL strategies:

(1) an opportunity to formatively interpret and judge for evidence of student learning and improvement (EL 1)

(2) an opportunity for students to demonstrate acquisition of understanding (EL 4), and

(3) opportunities for teachers to obtain and use information about students' progress towards learning goals (TP 1).

In order for the *Check Your Understanding* section to be considered AfL, the results of student work in these sections must be used to make instructional decisions. Thus, any code applied to the CME curriculum in this project can be seen as an element of the curriculum with the *potential* to become enacted AfL

Data Analysis

Coding the three data sources took place in two stages. The first stage coded the sources in the order mentioned in a previous section. After the preliminary coding, an initial analysis of this data was completed, triangulating among the three data sources. As the coding progressed from one source to another, more was learned about various elements of the curriculum. Specific design elements found throughout the curriculum received new codes over time. Through triangulation, the codes for a given element were combined from the three data sources, thus developing a more thorough coding scheme. With this new coding scheme, all three data sources were coded a second time, obtaining coding not found during the first round of coding. This ensured that items coded early on in the coding process had the updated code for that element.

The *Check Your Understanding* sections occur throughout the lessons in Chapter 1, and each of these sections was considered a single element of the curriculum. The IG states that "students should do Check Your Understanding exercises in class. By giving students some class time to work on these exercises, you can assess their preparation for individual work on the On Your Own exercises that follow" (p. 84). The *Check Your Understanding* exercises are intended to discover where students are in their learning for the purpose of formatively interpreting whether the students are ready to move on to the *On Your Own* exercises. From the framework (Figure 1), this curriculum element receives the codes EL 1 and TP 1.

During this process of triangulation, the SE helps show a different aspect of the *Check Your Understanding* exercises. This exercises focuses on eliciting evidence of student understanding:

"1. Derman opens a checking account on June 14. He records his check withdrawals and deposits, but he does not calculate his balance for a week. On June 20, the bank tells Derman that he has overdrawn his account.

a. When did Derman first overdraw his account?
b. How much money does he need to deposit to reach a positive balance?
c. How could Derman have avoided overdrawing his account?" (EDC, Student Edition, p. 14).

These three questions delve into the understanding students have about the mathematics. Thus, this section received the code EL 4.

The TE adds to what the SE brings to *Check Your Understanding* by offering multiple ways the teacher can elicit student understanding of the material: "**Exercise 1** Some students may never have used a checkbook ledger before. Explain what each column represents [in a checkbook ledger]. Explain the difference between a deposit and a check (withdrawal). You may wish to provide students with copies of Blackline Master 1.2 to complete" (EDC, Teacher Edition, p. 14). This peripheral segment points the teacher to possible *misunderstandings* students may have. This confirms the code EL 4 given when looking at the SE.

Therefore, the *Check Your Understanding* sections have the *potential* to be used formatively to change the direction of the lesson should students not be ready to move on in their learning (EL 1, PL 1). As this item elicits evidence of understanding, it had to be coded with EL 4. This process of triangulating using all three data sources to determine which codes to apply was duplicated for each element in the curriculum that was repeated throughout the chapter.

Results

Teacher Planning

Teacher planning yielded more codes that any other piece of the analytic framework. The Assessment Reform Group's 10 Principles of AfL (2002) focus so much on the idea that AfL must be pre-planned – they claim that AfL cannot just happen in the course of a lesson. Thus, it is crucial for a curriculum to present a teacher with AfL strategies. The CME curriculum offers numerous instances where opportunities are given for the teacher to obtain and use information about students' progress towards learning goals (TP 1) – see Figure 2. This necessarily requires that G 1 and G 3 be appropriately accomplished. In the SE, TP 1 occurs nine times through *In Class Experiments*, thirteen times through *Check Your Understanding*, and sixteen times through *Additional Practice* web codes.

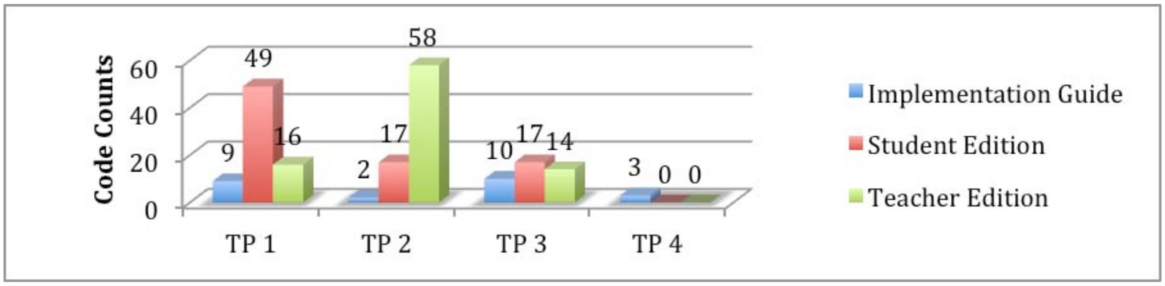

Figure 2: Teacher Planning Code Counts

Another aspect of AfL that is so important is the idea that instruction should change based on what students know and understand during a lesson (TP 2). The TE gives 58 such opportunities in the first chapter alone. Twelve occurrences of TP 2 came from *Additional Practice* sheets (the teacher could assign these based on the needs of their students), while thirty-one instances came from pacing suggestions. Pacing suggestions came in the form of exercises in the text being assigned as core problems (for all students to complete), extra practice worksheets (for those who need more practice), and extension problems (for those who understand the material thus far and can move on). As this chapter contains fifteen lessons total, a teacher averages two instances in class each day where they have the potential to make pacing and instructional changes.

One of the strengths in this curriculum is the intention that there is some flexibility with which the teacher can implement the curriculum. This flexibility enhances the learning for all students (TP 3) and encourages students to achieve their best (TP 4). Many of these instances come from the IG, which mentioned that it was the authors' goal to ensure that all students of CME have the opportunity to succeed at mathematics.

Goals

This category of the framework addresses the need for AfL to direct students toward the goals of learning. Of the three codes within this category, one of the three codes was never found (G 2). There were no instances where the curriculum suggested that students should partner with the teachers to set goals. The remaining two codes were used with the potential for AfL in mind – see Figure 3 for a summary of these code counts. Goals in the curriculum were similar to the following: "You will learn how to identify, describe, and justify patterns in arithmetic and in multiplication tables…You will develop these habits and skills: Gain a sense of how a mathematician works" (EDC, Student Edition, P. 8). These goal statements were in the curriculum using student friendly language (G3). They also have the potential to be G1 (students understand the goals of learning) if the teacher actually has the students read through them as well as keep the goals in mind throughout the lesson.

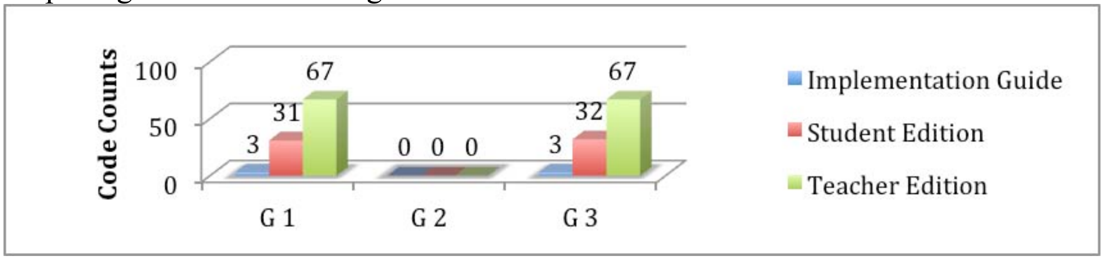

Figure 3: Goal Code Counts

Evidence of Learning

In order for the first AfL question to be answered (Wiliam & Thompson, 2007), evidence of learning must be elicited. A vast majority of these codes come from the SE – see Figure 4. The first code is another of the major codes that has the potential for being AfL. In the first chapter, teachers have the opportunity to formatively interpret and judge for evidence of student learning and improvement 72 times combined in the three data sources. The key word in this code is *formatively*, where the teacher has the chance to change the direction of student learning based on current levels of skills, knowledge, and understanding. This means that the interpretations must take place in order to change instruction. This includes any assessment item completed at home as well as those completed in class. In the first chapter, the curriculum materials include 51 opportunities to elicit knowledge, 48 opportunities to elicit skills, and 92 opportunities to elicit understanding.

Six categories of student exercises contain most of the codes for Evidence of Learning. *Check Your Understanding* occurred thirteen times in the chapter, and contained EL 1 and EL 4. *For You To Do* occurred twenty times, coded with EL 2 and EL 3. *Maintain Your Skills* occurred sixteen times, as did *On Your Own, Take It Further, and Additional Practice*. Codes used for these four sections were EL 3; EL 2 and EL 4; EL 4; and EL 1, respectively.

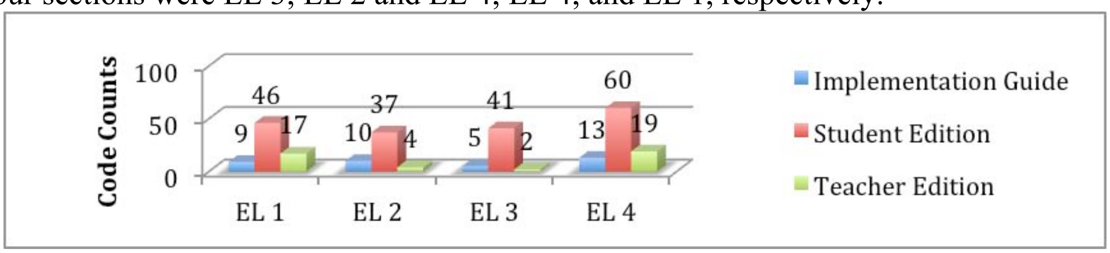

Figure 4: Evidence of Learning Code Counts

Constructive Feedback

Feedback is the backbone of the AfL literature (Black & Wiliam, 1998b; Wiliam & Thompson, 2007). The IG, SE (Chapter 1), and TE (Chapter 1) did not contain a single instance of constructive feedback. Constructive feedback is required for AfL to be completed (Sadler, 1989). There were numerous instances where the TE suggested ways for teachers to work with student answers. However, since these instances did not both point students to where they should go and how to get there, these could not be classified as constructive feedback.

Discussion

Overall, the first chapter of CME Algebra 1 presents learning goals in student-friendly language. The curriculum has great potential for ensuring students understand these goals. If a teacher endeavors to enact AfL, this curriculum will help begin that process by clearly outlining the learning goals prior to learning. In order for this potential to be realized, the teacher must do more than simply place these goals in front of the students. As the analytic framework suggests, teacher plans should ensure that information is elicited about students' progress toward these goals (TP 1). These goal statements also help to answer the second AfL question: Where are students going? (Wiliam & Thompson, 2007). CME Algebra 1 accomplishes this.

The numerous instances where students have the opportunity to show their knowledge, skills, and understanding help the teacher to have the chance to formatively interpret this evidence for further instruction. Moreover, the teacher is directed to use this information to make instructional decisions. This process helps answer the first AfL question: Where are students at in their learning? (Wiliam & Thompson, 2007). The CME curriculum offers the teacher opportunities each day of class to make instructional decisions based on where students are at in their learning. It is not enough that teachers simply find out where students are at in their learning – the teacher must change their instruction to help the students move on.

The final AfL question, directly related to feedback, is not addressed in the CME Algebra 1. This would mostly come through feedback. The fact that this major piece of AfL is missing could lead one to believe that the CME Algebra 1 curriculum does not accomplish this strategy of AfL. Bringing in the concept of potential for AfL, though, helps temper this major gap. In other words, the CME Algebra 1 curriculum has the potential to answer the first two AfL questions all by itself. The teacher still must enact these pieces of the curriculum. If these are enacted, then the teacher, outside of what the curriculum brings to the classroom, has the potential to put constructive feedback into the classroom on their own to complete the three AfL questions.

Because CME Algebra 1 helps answer the first two AfL questions, it does have the potential to provide the conditions under which AfL can be enacted. The key to making this so is how the teacher decides to use the curriculum. The teacher must decide whether or not they will take the time to not only go through the goals of learning with the students, but also point back to these learning goals throughout the learning process, especially as they elicit evidence of student learning. The lack of information the curriculum brings to help answer the final AfL question leads me to conclude that this curriculum is not a complete, pre-packaged, AfL curriculum but it does have great potential to enact AfL in the classroom.

Endnotes

This research was funded by the National Science Foundation, under Project Contract (DRL-0733590). All views in this report are those of the author and do not represent the views of the National Science Foundation.

ASSESSING SECOND GRADERS' MATHEMATICAL COMMUNICATION ON A STANDARDIZED TEST

Lucia M. Flevares
The Ohio State University
flevares.1@osu.edu

Susanna Owens
University of Michigan
susanna.owens@gmail.com

The processes of communication and representation are essential mathematical ways of thinking, and assessments can provide opportunities to evaluate the evidence of their communication and representation of their problem solving. We examined the pretest and posttest responses to an open-ended story problem of 83 second-grade students from four classrooms. The implemented coding system differentiated the responses not only by the correctness of the response, but also by how explicitly the strategy or solution process had been communicated. We found that not only did students' responses show evidence of greater communication of strategy and process from pre- to posttest, but that answer accuracy was associated with well-communicated responses. Our results provide the grounds for emphasis on process communication in early elementary school and for future investigation into effective instruction and assessment.

Young Children's Communication of Mathematical Thinking

Variations of the idea that "the answer is not enough" pervade current mathematics teaching at all levels (e.g., Sterenberg, 2004). Intertwined with mathematics students' ability to use strategies to solve problems is their ability to communicate their mathematical thinking effectively – to show more than that final answer. According to the National Council of Teachers of Mathematics (2000), communication offers "a way for students to articulate, clarify, organize, and consolidate their thinking" (p. 128). For young mathematics students, in particular, to use strategies effectively, especially for more advanced arithmetic such as multi-digit subtraction, they must be able to "organize subgoals into a coherent process without getting lost within particular subgoals" (Fuson et al., 1997, p. 151).

To support learners' mathematical communication, teachers' instruction should emphasize documenting their solution processes. Whitenack, Knipping, Novinger, and Underwood (2001) studied a second-grade class during a unit on multi-digit addition and subtraction. Throughout the unit, the teacher emphasized students' organization of recording the regrouping process, applying strategies across multiple contexts, and sharing their processes. This instructional sequence not only allowed students to deepen their understanding of multi-digit operations, but also fostered organized problem solving and communication for their benefit and for the benefit of their peers and the teacher.

Assessment of Children's Mathematical Understanding and Communication

In spite of the emphases on problem solving and communication in instruction, assessments have traditionally focused largely on students' ability to reproduce facts and computational procedures (Pegg, 2002). Problem solving and communication are essential mathematical skills, and thus, assessments should focus not only on students' accuracy, but also on the *quality* of students' thinking (Pegg, 2002; Cai, Jakabcsin, & Lane, 1996; NCTM, 2003).

In the early elementary grades, when students are just learning to communicate in written form, assessments of students' problem solving and communication skills can be challenging to design. On the other hand, written assessments are often the most efficient to administer, compared to other methods that might yield problem-solving insights such as observation or interviews with students. Thus, well-designed written assessments hold the potential to assess students' problem solving and be efficient to administer, but these assessments should not only include ways to incorporate students' communication of their solution process, but also ways for evaluators to make sense of these responses to maximize the information they yield. Open-ended tasks, scored with a holistic rubric, may be effective to assess the quality of students' thinking (Cai, Lane, & Jakabcsin, 1996).

In the present study, we examined the quality of second-graders' responses on an open-ended mathematics task that dealt with multi-digit subtraction concepts. We were specifically interested in examining how students' communication and representation of their thinking changed over the course of an academic year. We were also interested in examining possible connections between quality of communication and accuracy.

Method

Data Source

In order to explore these questions, we examined pre- and post-test responses to an Ohio Department of Education second-grade assessment, designed to provide diagnostic information about students' ability to meet the second-grade state content standards. We chose to examine students' responses to one open-ended, constructed response item which read: *A girl has a dollar. She wants to buy a new pencil for 76 cents. How much money will she have left after she buys a pencil? Show how you found your answer.* This item had several key features: it addressed multi-digit subtraction concepts, important grade-level content, its story problem format required students to identify and apply an appropriate operation, and it involved money, which poses both conceptual and representational challenges for students. Finally, we felt that the open-ended format of the question would yield a rich and diverse range of responses.

Participants

We examined the responses of 83 second-grade students from four classes in a suburban primary school for whom both pretest (October) and posttest (May) scores were available. The students came from four classrooms. A mathematics coach worked with two of the four classrooms for several weeks during the year.

Coding

Coding Scheme. Our interests were centered on the quality of students' communication and representation of their mathematical thinking. The state-supplied three-point rubric for this item did not differentiate responses based on the quality of students' communication, so we decided to design a new rubric with this specific purpose (see Appendix). Our rubric categorized responses into five major levels of quality of communication, including responses: 1) that showed no work, 2) that showed some work but did not provide evidence of strategy use, 3) that provided evidence of an inappropriate strategy, 4) that provided evidence of an appropriate but insufficiently communicated strategy, and 5) that sufficiently communicated an appropriate strategy. Within each of these five levels, the score for a correct answer was given one point more than the score for an incorrect answer. We reserved the highest score (10) for responses that included an especially clear communication of a student's thinking either by demonstrating how their work was connected to the givens in the problem or by using multiple representations to communicate their thinking. Two coders achieved 90.1% simple agreement, periodically performing coding checks and ultimately reaching agreement on all coding.

Analysis. Upon coding completion, we calculated the frequency of responses that received each value on our rubric. Within each of the five main categories of communication quality, we examined scores for differences between correct and incorrect responses, with regard to communication quality and accuracy.

Results

From fall to spring, the mean scores increased not only in accuracy but also in the students' mathematical communication, from an overall mean score of 3.95 (of 10) in autumn to 5.77 in spring. Examining the responses more closely, we also observed trends in the way that students' mathematical communication and strategy use was correlated with their accuracy. We used the frequency of each response type to determine the percentage of correct and incorrect responses that were given within each level of communication. For example, of the 20 responses in which no work was shown, only 2 (10%) were correct. Similarly, we observed low rates of correct responses that used no identifiable strategy (35% of 26 responses) or an incorrect strategy (19% of 30 responses). Unsurprisingly, students who did not record appropriate strategies were less likely to provide correct answers than those students who did.

What was more notable, though, was the trend among responses that *did* indicate the use of an appropriate strategy. Our scoring rubric included two categories of responses that used an appropriate strategy but differentiated those that were sufficiently communicated (either an 8 or 9) from those that were not (either a 6 or 7). The difference between insufficient and sufficient communication, even when an appropriate strategy is used, does matter in terms of accuracy: while 92% (23 of 25) of the well-communicated responses yielded an accurate answer (see Figure 1), only 54% (23 of 50) of the insufficiently communicated responses yielded an accurate answer. This association between correctness and explication of mathematical communication provides a rationale for encouraging the development of communication in problem solving.

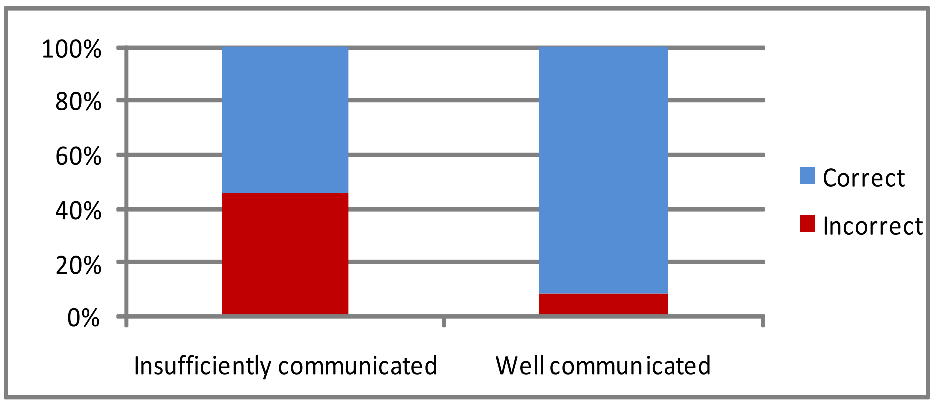

Figure 1: Proportion of Correct and Incorrect Responses for Two Types of Appropriate Responses

Although we were not able to conduct classroom observations, the student data came from four classrooms in the same school, and we examined the student responses by classroom for trends in responses. We found that the students in the coached classrooms, classrooms 1 (mean improvement of 2.76 points) and 4 (2.57 points) improved more on average than students in the uncoached classrooms, classrooms 2 (1.22 points) and 3 (0.63 points). When we looked at each class's spring data, we found that certain forms of communication and strategy use were favored by certain classes: in class 1, many responses (43%) included drawn coins; in class 2, a plurality of the responses (30%) used tally marks, used by none of the students in the other classes; Class 3 had the highest percentage of responses (74%) which included subtraction sentences. Within these, half had subtraction sentences shown both horizontally and vertically, and 43% showed the partial differences (e.g. 100 – 70 = 30; 30 – 6 = 24; 100 - 76 = 24), used by respondents in no other class. In class 4, a majority of responses (57%) involved drawing base ten blocks, while only 3 responses from other classes did.

The mathematics coaching experienced in two of the classrooms focused on engaging students in problem solving and developing their understanding of the five NCTM mathematical processes, including communication and reasoning and proof. We note that in Class 4, one of the coached classrooms, predominant responses involved multiple representations, including base-ten iconic representations, and in the other coached classroom, students favored another iconic representation, the coins. In the uncoached classrooms, students favored either basic iconic representations, tally marks to count (Class 2), or numeric equations. The relation between teachers' instructional and expectations for students' responses within class and students' methods of communication on standardized assessments merits further investigation, but these by-classroom trends support the idea that specific expectations for students' mathematical communication can be taught and that students respond to instruction about how to communicate their thinking.

Discussion

In our study, we sought to examine students' mathematical communication and strategy use on an open-ended story problem task on a standardized assessment, and we documented the relation between students' mathematical communication and answer accuracy on the mathematics assessment. Traditionally, mathematics educators and assessments may have emphasized accuracy more than communication, but our results suggest that good communication may support accuracy.

In examining the differences between insufficiently communicated responses and well-communicated responses, we found that students' organization and labeling of their work was associated with both the clarity of their communication and their accuracy. Teachers can help students learn to communicate their mathematical thinking clearly and support students' accuracy on mathematical tasks by encouraging them to record their thinking in an organized and well-labeled manner. In tasks like the one studied, teachers could emphasize the importance of labeling drawings clearly by encouraging students to cross out the coin or base-ten block that they are partitioning and draw an arrow to the group of coins or blocks that they have drawn in its place. More generally, teachers should expect students to "show their work" and should provide ongoing opportunities for students to engage in mathematical communication and by offering feedback on students' communication of their mathematical thinking.

Our study also has implications for those who design mathematics assessments for early grades children. With mathematical communication as an important goal for instruction, designers of standardized mathematics assessments should ensure that students' communication is encouraged, clearly stated as an expectation, and measured. With such provisions built into assessment tasks, test results could provide more specific, and thus, more formative, information about students' performance. While the rubric used for this study is likely more detailed than a rubric a school district would use, it is important that scoring rubrics give some attention to mathematical communication. Assessing students' communication on standardized mathematics assessments not only emphasizes that communication is an essential component of mathematics, but it also gives teachers and district staff evidence of strategies and different representations that students used. Future investigations will involve classroom observations and documentation of instruction and student work to identify the processes that lead to growth in students' mathematical communication.

Appendix: Scoring Rubric

10 Response is very well articulated; as is evidence by:

- *A clear connection between student work and the information given in the problem. (e.g. indicates that the initial value is $1.00 rather than simply representing the number 100)*
- *The presence of multiple clear representations of the strategy used (e.g. student includes a clearly labeled drawing of base-ten blocks AND a subtraction sentence)*

9 Response is correct and well communicated. An appropriate strategy is used.

8 Response is incorrect, but well communicated. An appropriate strategy is used.

7 Response is correct and there is evidence that an appropriate strategy was used. However, the process of arriving at an answer is not well enough communicated. This may occur as the following:

- *A response including a subtraction sentence does not communicate the solution steps.*
- *A response including a counting strategy is disorganized, and thus requires some inference on the part o the evaluator.*
- *A response including drawings of coins or base-ten blocks does not label trades that were made, requiring some inference on the part of the evaluator.*

6 Response is incorrect, but there is evidence that an appropriate strategy was used. However, the process of arriving at an answer is not well communicated. This may occur in any of the following ways:

- *A response including a subtraction sentence does not communicate the solution steps.*
- *A response including a counting strategy is disorganized, and thus requires some inference on the part o the evaluator.*
- *A response including drawings of coins or base-ten blocks does not label trades that were made, requiring some inference on the part of the evaluator.*

5 Response is correct; there is evidence of a strategy, but it is not appropriate for the problem.

4 Response is incorrect; there is evidence that a strategy was used, but the strategy is not appropriate for the problem or does not seem to be connected to the problem.

3 Response is correct, but no identifiable strategy is used. Some work is shown, such as a representation of coins or tallies, but there is no evidence of the process used to get an answer.

2 Response is incorrect, and no identifiable strategy is used. Some work is shown, such as a representation of coins or tallies, but there is no evidence of the process used to arrive at an answer.

1 Response is correct, but no work is shown.

0 Response is incorrect, and no work is shown.

CALCULUS READINESS: COMPARING STUDENT OUTCOMES FROM TRADITIONAL PRECALCULUS AND AP CALCULUS AB WITH A NOVEL PRECALCULUS PROGRAM

Rusen Meylani — Arizona State University — Rusen.Meylani@asu.edu

Dawn Teuscher — Brigham Young University — Dawn.Teuscher@asu.edu

This comparative study examines three groups of high school students' understanding of the foundational concepts needed for calculus. Students completed one of three courses: (1) traditional precalculus, (2) novel precalculus, or (3) Advanced Placement (AP) Calculus AB. Student scores on the Precalculus Concept Assessment (PCA) and two open-ended tasks which focused on functions and rate of change provided the data. Student work was analyzed for strategies employed and efficiencies with their strategies on the two tasks. The results revealed that students who completed the novel precalculus curriculum gained a deeper understanding of the fundamental concepts for calculus by performing higher than the traditional precalculus students and comparably to the AP Calculus AB students.

Introduction

Precalculus is a mathematics course offered in high schools across the United States with approximately 18.5% of all high school students enrolling during their third or fourth year of high school. Yet a growing student population is required to enroll in precalculus when they enter college because they either did not complete it in high school, but more often students do not score high enough on the individual college mathematics placement exams and therefore are required to enroll in a course they may have completed during high school. Parents, students and educators are asking: (1) What are students not learning in high school precalculus that is causing them to have to retake the course when they enter college and (2) What mathematics content is missing from the high school precalculus curriculum that could help students better prepare to enter college calculus?

Over the past 20 years researchers have focused on college students understanding of function and the different reasoning patterns they need to be successful in higher level mathematics, such as calculus (Breidenbach, Dubinsky, Hawks, & Nichols, 1992; Carlson, 1998; Carlson, Jacobs, Coe, Larsen, & Hsu, 2002; Carlson & Oehrtman, 2005; Engelke, Oehrtman, & Carlson, 2005, October; Ferrini-Mundy & Gaudard, 1992; Ferrini-Mundy & Graham, 1991, 1994; Markovits, Eylon, & Bruckheimer, 1988; David Tall, 1992; David Tall, 1997; Thompson, 1994a, 1994b). However, less research has been conducted at the high school level to understand what secondary students who are enrolled in precalculus understand or do not understand about function and if the reasoning patterns and frameworks used for undergraduate students can or should be applied to high school precalculus students. Therefore, in this study we seek to answer the following two research questions: (1) How do high school precalculus students who used either a traditional precalculus curriculum or a research based conceptually–oriented curriculum compare on the foundational concepts needed for calculus and their efficiency and use of mathematical strategies? (2) How do high school precalculus students who completed a conceptually-oriented curriculum compare with AP Calculus AB students on the foundational concepts needed for calculus and their efficiency and use of mathematical strategies?

Theoretical Framework

The concept of function is an essential knowledge students need to be successful in higher level mathematics. For students to understand the concept of function they must first obtain a process view of function (Breidenbach et al., 1992), meaning they understand that they are mapping a set of input values to a set of output values and it is a continuum. Second, students must develop covariational reasoning (Carlson, 1998), described as "the cognitive activities involved in coordinating two varying quantities while attending to the ways in which they change in relation to each other" (Carlson et al., 2002, p. 354).

Typically precalculus teachers and the curriculum they use focus student attention on learning the algebraic manipulations and procedures rather than the conceptual understanding of function that provides foundational knowledge needed to build on for studying higher level mathematics. Breidenback et al. (1992) and Dubinsky and Harel (1992) described two views of functions students have: *action* or *process*. An action view of function is described as "the ability to plug numbers into an algebraic expression and calculate" (Dubinsky & Harel, 1992, p. 85). Students tend to think about the function in a procedural way as they input a value into a specific function to calculate the correct output doing "plug and chug" without any conceptual understanding of function which may eventually hinder their understanding of calculus concepts such as limit, derivative, and integrals.

Carlson and Oehrtman (2005) extended Breidenbach et al. (1992) and Dubinsky and Harel's (1992) research on the action and process views students have of function arguing that student's ability to answer function focused tasks was related to two types of reasoning.

> First, … students must develop an understanding of functions as general processes that accept input and produce output. Second, they must be able to attend to both the changing value of output and rate of its change as the independent variable is varied through an interval in the domain. (Oehrtman, Carlson, & Thompson, 2008, p. 5)

For example, students who hold an action view of function have multiple misconceptions about piecewise functions being several functions and do not reason over an entire interval. Students tend to focus on specific points instead of interpreting the entire function. They also tend to not relate the domain and range to the inputs and outputs of the function. Without an understanding of functions accepting inputs and producing outputs students will struggle to reverse (inverse functions) the process. Most students are able to find the inverse of a function algebraically (switch the x and y and solve for the y variable) or geometrically (reflect the function over the line y = x); however, their answer typically has no meaning (Carlson & Oehrtman, 2005). Students who hold an action view are able to work with functions procedurally, but have little conceptual understanding.

On the other hand, students who hold a process view of function can imagine an entire function and how the input values affected the output values. This is described as covariational reasoning, the ability to vary inputs and outputs at the same time and interpret or understand their influence on the rate of change. Students who demonstrate a process view of inverse functions use a reversal process that defines a mapping of output values to input values. A process view of function is essential for understanding calculus concepts such as the limit, derivative, and integral.

Carlson, Oehrtman, and Engelke (2010) developed a taxonomy of foundational knowledge for beginning calculus representing the key concepts of precalculus students should know and understand prior to entering calculus. The *PCA* taxonomy was used to develop the *Precalculus Concept Assessment (PCA)*, a 25 multiple–choice item exam that assesses rate of change, function, and covariational reasoning that students will build upon in their study of calculus. The *PCA* and PCA taxonomy have gone through multiple refinements as research on student thinking is conducted (Carlson et al., 2010). Although the details of the PCA taxonomy are not part of this paper it is imperative to note that the existence of such a taxonomy is one of the reasons why the *PCA* is a valid tool for assessing students understanding of the foundational concepts of precalculus prior to entering calculus.

The *PCA* was developed over a 15 year time period based on numerous college students' interviews of what they thought and understood as they answered open–ended questions about functions. The distracters on the *PCA* are common misconceptions that college students have about functions (Carlson et al., 2010). More recently, the *PCA* was used by high school precalculus teachers to determine their students' understandings and misconceptions after completing the year long course and entering AP calculus (Teuscher, 2008). These data were influential in helping teachers discover holes in their mathematics curriculum and making changes to help students develop the key precalculus concepts prior to entering calculus.

Methods

In this study we examined high school students' understanding of the foundational concepts of calculus as described by the *PCA* and two open–ended tasks focused on rate of change. We coded students' strategies in solving these tasks and compared their efficiency in using the strategies. In this section we describe the instruments and participants.

Precalculus Concept Assessment

The *PCA* was developed by faculty from the Department of Mathematics at Arizona State University and was designed to reflect core content and common misconceptions students have about functions (Carlson et al., 2010). Carlson et al. (2010) administered the *PCA* to 902 college precalculus students and found the "Cronbach's alpha of 0.73 indicating a high degree of overall coherence" (p. 137). Carlson and colleagues also conducted clinical interviews with more than 150 college students so as to validate the *PCA* items. Each question was tested and validated to guarantee that students who selected a specific distracter (i.e., answer choice) consistently provided similar justifications during interviews (Engelke et al., 2005, October).

Open–ended Tasks

The *Piecewise Functions* (*PF*) task was adapted from a released 2003 AP Calculus free response item by an AP Calculus teacher for precalculus students; it gives students the graph of a piecewise function and has them find rates of change and then write equations for the function. The *Filling the Tank* (*FT*) task was taken from examples developed by Peter Taylor (1992) and it requires students to compare average flow (rate of change) with instantaneous flow as water is flowing in and out of a tank simultaneously. Both tasks build on the foundational concepts of functions and rate of change that students need before calculus and require students to use reasoning and demonstrate their understanding of the meaning of functions; however, one task is based in a contextual setting and the other is not.

Students worked on the two tasks individually during a scheduled class period during the first week of class and the student work was scored for correctness using scoring guides and coded for solution strategies on specific questions for both open–ended tasks. The items coded for solution strategies were *PF* questions 1, 2 and 4 and *FT* questions B and E. The five categories of strategies were: Formula, Graph, Table, Multiple, and None or can't tell. The scoring guides for the open–ended tasks required 22 scoring decisions on each of the *PF* and *FT* tasks and the average reliability of scoring was 95% and 96% for the *PF* and *FT* tasks respectively.

Participants

High school students from Rover High School located in the southwestern region of the United States, who completed either Precalculus or AP Calculus AB during the 2009-2010 school year and enrolled in AP Calculus BC for the 2010–2011 school year were asked to participate in the study. All mathematics teachers at Rover High School are part of a National Science Foundation Math and Science Partnership grant (No. EHR–0412537). The students in this study (N = 36) were taught by one of four different teachers in their previous mathematics course (Precalculus or AP Calculus AB). Four mathematics teachers taught students in precalculus during the 2009–2010 school year. Three of the four teachers used *Precalculus: Mathematics for Calculus* (Stewart, Redlin, & Watson, 2005) and the fourth teacher used a research based conceptually–oriented curriculum *Precalculus: A Pathway to Precalculus* (Carlson & Oehrtman, 2010). All precalculus students took the *PCA* at the end of the 2009–2010 school year. Students who enrolled in AP Calculus BC for the 2010–2011 school year completed the two open–ended tasks, *PF* and *FT* during the first week of class.

Please note that the three groups of students were not selected deliberately; they naturally emerged as a result of the mathematics classes they were enrolled and the choice of curriculum followed by their teachers. As a matter of fact, only one teacher chose to use *Precalculus: A Pathway to Precalculus* and this is how the PP students, who are of major interest in this paper, were selected.

Results

The goal of this study was to assess student understanding of the foundational concepts for calculus. Therefore, we compared precalculus students' performance based on the curriculum they used. We also compared the precalculus students (N = 25) who used the Pathways curriculum to the AP Calculus AB students (N = 11) who enrolled in AP Calculus BC the following year. To summarize and clarify, the three groups of students of interest in this study were: (1) students who were taught using P*recalculus: Mathematics for Calculus* (Stewart et al., 2005), which we refer to as Traditional Precalculus (TP; N = 11); (2) students who were taught using *Precalculus: A Pathway to Precalculus* (Carlson & Oehrtman, 2010), which we refer to as Pathways Precalculus (PP; N = 14); and (3) students who completed AP Calculus AB which we will refer to as AP Calculus AB (AB).

The analyses in this study are presented in four parts. First, we provide descriptive and comparative analyses to compare the PP students with both the TP students and the AB students. Second, we present a breakdown and distribution of student scores to the items on each task and compare the PP students with the other two groups (TP and AB). Third, we describe the solution strategies used by students based on the three groups. Finally, we compare the effectiveness of students' solution strategies for the PP students with the other two groups (TP and AB).

Statistical analyses and descriptives

The first analysis compares TP and PP students; in order to identify whether these groups were statistically different prior to entering AP Calculus and completing the open–ended tasks the *PCA* scores were compared. A t–test was conducted and PP students had a statistically significant higher mean on the *PCA* than TP students (t = –3.37, p = .003); therefore, further analysis to compare students' performance from these two groups on the open-ended tasks used *PCA* scores as a covariate to account for difference in learning prior to entering AP Calculus BC.

An analysis of covariance (ANCOVA) was conducted to determine the statistical difference between the mean total score on the *PF* task for the two groups (PP and TP) of students adjusted for *PCA* scores. No statistically significant difference was found between the two groups (PP and TP) for the mean total score on the *PF* task (F = 0.98, p = 0.333). A similar analysis was completed to determine the statistical difference between the mean total score on the *FT* task for the two groups (PP and TP) of students adjusted for PCA scores. Results indicated no statistically significant difference between the two groups (PP and TP) for the mean total score on the *FT* task (F = 0.20, p = 0.658).

An analysis of variance (ANOVA) was conducted to determine the statistical difference between the mean total score on the *PF* task for the two groups (PP and AB) of students. Results indicated no statistically significant difference between the two groups (PP and AB) for the mean total score on the *PF* task (F = 0.10, p = 0.753). A similar analysis was completed to determine the statistical difference between the mean total score on the *FT* task for the same two groups of students. No statistically significant difference was found between the two groups for the mean total scores on the *FT* task (F = 2.10, p = 0.161).

PCA scores for the AB students were not available because data collection on precalculus students for the MSP project began the year these students were in AP Calculus. However, the results of the two ANOVA's confirmed that there was no statistically significant difference between the PP and AB students for the mean total scores on both open-ended tasks meaning these students' prior knowledge was similar.

Breakdown and distribution of the scores

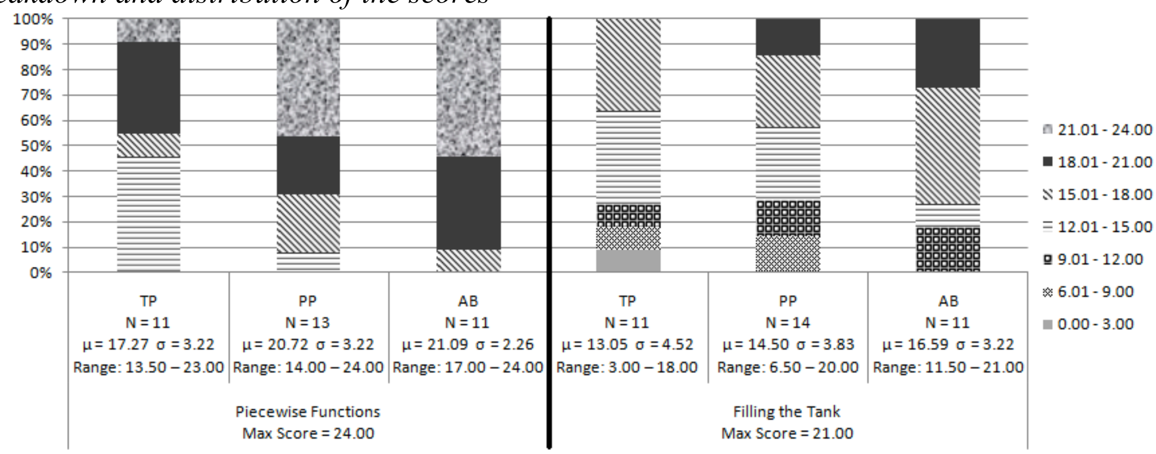

Figure 1. Score distributions on the total scores of the PF and FT tasks for the three groups of students

The distributions of the total scores for the three groups of students on the PF and FT tasks are displayed in Figure 1. For the PF task, respectively, 45% and 55% of the PP and AB students scored higher than 21 out of the total score of 24 while only 9% of the TP students scored in this range. Approximately 37% of the TP and AB students scored between 18 and 21 inclusively, out of 24. The TP group had the greatest percentage (37%) of students receive a score in the 15.01 – 18.00 range with 36% of AB students and 22% of PP students scoring in the same range. Finally, the standard deviation (3.22) was the same for the PP and TP students whereas it was less for the AP Calculus AB students (2.26).

For the *FT* task, respectively, 37%, 28%, 10% of the TP, PP and AB students scored in the 12.01 – 15 range. Meanwhile, 46% of the AB students, 37% of the TP students and 28% of the PP students scored in the 15.01 – 18 range. Although none of the TP students scored in the highest range of 18.01 – 21.00, 14% of PP students and 27% of AB students scored in this range.

Finally, the standard deviation was the greatest for TP students (4.52); whereas, the AB students had the smallest (3.22).

Distribution of the solution strategies

The distributions of the strategies for all three groups on items 1, 2, and 4 of the *PF* task and items b and e of the *FT* task are shown in Figure 2. For item 1 of the *PF* task, 77% of the PP students, 55% of the TP students and 37% of the AB students used graphing as their solution strategy. While none of the PP students used a formula, approximately 45% of AB students and 18% of TP students employed this strategy. Finally 18% of the PP students used multiple strategies.

For item 2 of the *PF* task, graphing again was the dominant strategy for a considerable number of students. PP students used graphing the most (77%); while the AB students used this method the least (37%). None of the PP students used the formula strategy; however, approximately 18% of AB students and 10% of TP students employed this strategy. Only PP students (7%) used multiple strategies when solving this question. The AB group had the highest percentage (46%) of students whose work for this item revealed no strategy and the TP group had a slightly less percentage (36%); however, the PP group only had 16% of students whose work did not reveal a strategy.

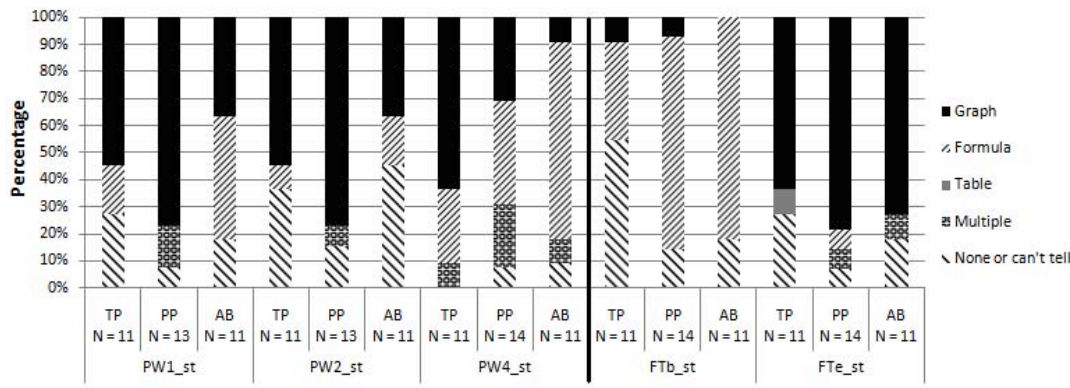

Figure 2. Distributions of strategies for the three groups of students on both of the open ended tasks.

For item 4 of the *PF* task, the TP group had the highest percentage (64%) of students who used graphing to solve this item. The PP group had the highest percentage (23%) of students who used multiple strategies, typically graphing and formula strategies, to solve this item. The AB group had the highest percentage (74%) of students who used a formula to solve *PF* item 4. Only 8% of PP and 9% of AB students work was not possible to code for a strategy.

For item b of the *FT* task, the dominant strategy was formulas for all three groups. Of the TP students, 36% used formulas, 9% used graphing and the remaining students it was not possible to code for a strategy. Of the PP students, 79% used formulas, 7% used graphing and the remaining 14% of the students it was not possible to code for a strategy. The majority (82%) of the AB students used formulas and the remaining 18% of students it was not possible to code for a strategy.

For item e of the FT task, the dominant strategy (graphing) was the same for all three groups; respectively 64%, 79% and 74% of the TP, PP and AB students used this strategy. Only TP students (9%) used tables and this was the only instance where tables were employed as a strategy. The PP group had 7% of students use formulas; whereas, 7% of PP and 8% of AB students used multiple strategies. The TP group had the largest percentage of students (27%)

whose work was not able to be coded for a strategy, while the PP group had the lowest percentage (7%). The percentage of students for whom it was impossible to tell which strategy was used was the smallest for the PP group on items 1 and 2 of the *PF* tasks and items b and e of the *FT* task.

Simultaneous Comparison of the Solution Strategies and Scores for Evaluating the Efficiency among the Groups

While it is interesting to indicate strategies students used in solving the open-ended task, it is also vital to know their respective efficiencies (i.e. what strategies do students use when they receive higher scores?). For this purpose we examined simultaneously the scores and strategies to assess for each group the strategies employed within each score range. Particular interest was given to the students who could score 19 or above out of 24 on the *PF* task and 14 or above out of 21 on the *FT* task; these students constituted the majority (approximately 70%) of the PP and AB students and a minority (35%) of the TP students. For this highest scoring group, the dominant strategies were graphs and formulas, although AB students preferred formulas to graphs whenever they could whereas this was the opposite for the PP students. The TP students in this group primarily used graphs as well.

Discussion

This study assessed students' understanding of foundational concepts of calculus. Two open-ended tasks were used to compare students' understanding after completing a precalculus or AP Calculus course, yet prior to entering AP Calculus BC. Thus, there was a gap of three months between the administration of the open-ended tasks and the last time students were in school learning mathematics.

The statistical tests that compared the TP and PP students showed no statistical significant difference between these two groups based on their performance on the tasks; however, the statistical tests accounted for prior achievement by using the *PCA* scores as a covariate. The *PCA* is a powerful assessment tool used for evaluating students' understanding of the key concepts in precalculus (Carlson et al., 2010). The fact that the PP students mean *PCA* scores are statistically higher than the TP students mean *PCA* scores indicates that the PP students have a significantly better understanding of the key concepts in precalculus when compared to the TP students. Moreover a second conclusion is that the mean total score for the PP students on the open-ended tasks were consistently higher than those of the TP students. The PCA scores for the AB students were not available.

The statistical tests that compared PP and AB students showed no statistically significant difference between their mean scores on the two open-ended tasks (*PF* and *FT*); specifically, on individual items and total scores. The existence of no statistically significant differences between these groups (PP and AB) is particularly remarkable since theoretically the AB students should have performed better than precalculus student on the foundational concepts of calculus as they were exposed to a whole year of calculus. Yet, the AB students did not perform better than the PP students, which could be interpreted as AB students did not learn the foundational concepts of calculus deeply enough to retain them for three months over the summer break; however, the PP students did. This result also suggests that the precalculus curriculum, *Precalculus: A Pathway to Calculus* (Carlson & Oehrtman, 2010) is different than the traditional precalculus program.

In fact, *Precalculus: A Pathway to Calculus* was specifically designed to deepen the understanding of mathematical concepts by improving the learners' exploratory skills through analysis and synthesis; the learners in this curriculum continually study mathematical and scientific contexts and use mathematics as a means to perform scientific investigations. Accordingly, the classroom practice is shifted from the delivery of curricular material to inquiry and project-based approaches centered on content. This study proves that such a shift will help students develop a deeper and longer lasting understanding of the foundational concepts of calculus.

The sample sizes were 11 for the TP and AB students while it was 13 or 14 for the PP students. This is a considerable limitation which could have created power issues, however, this study was indeed a pilot one, carried out to assess the effectiveness of the *Precalculus: A Pathway to Calculus* program. Nevertheless, the relatively smaller sample sizes did not hinder the ability of the authors to come to statistically significant conclusions about the superior aspects of the program.

Based on the results of this study, the *Precalculus: A Pathway to Calculus* is likely to create a positive impact on the precalculus knowledge of students prior to entering calculus.

PRECALCULUS CONCEPT ASSESSMENT: A PREDICTOR OF AP CALCULUS AB AND BC SCORES

Rusen Meylani
Arizona State University
rusen.meylani@asu.edu

Dawn Teuscher
Brigham Young University
dawn.teuscher@asu.edu

This study establishes a theoretical framework for predicting the American College Testing (ACT) Mathematics and AP Calculus AB and BC scores from the Precalculus Concept Assessment (PCA) exam results and suggests a total of 16 different regression based models to actually perform the prediction. The strong positive correlation between the actual and predicted values confirm that the PCA is a powerful tool for identifying students who are at the risk of not passing AP Calculus AB or BC tests and thus help teachers, parents and students to take the necessary measures in a timely manner.

Introduction

Assessments are a major practice in the K-12 educational system as well as post secondary. High school students are required to take more and more assessments to demonstrate what they have learned. Most states require high school students to take either an end of course (mathematics) exam and/or a graduation exam (with a portion being mathematics) to complete a course or to graduate from high school (Teuscher, Dingman, Nevels, & Reys, 2008). In addition, most colleges require students to take a mathematics placement exam to direct students into the appropriate first year mathematics course. Even though students are required to send official transcripts and take one of the college entrance exams, they are being asked to demonstrate their knowledge of mathematics on multiple assessments.

Math placement exams vary in mathematics content, the number and type of questions (multiple choice, open-ended, etc.), use of calculators, and time limits. The number of different mathematics placement exams used by institutions across the country continues to increase. However, there are only two commonalities among these placement exams (1) the focus of exam items is on content and procedures taught in remedial mathematics classes, which satisfy general education requirements or serves as prerequisites such as college algebra and precalculus; and (2) the results are not used to inform student or teachers of the possible deficiencies in student knowledge.

This article reports research results on how high school students performed on the AP Calculus AB or BC exam, the Mathematics portion of the standardized *American College Testing* (*ACT*) and on the *Precalculus Concept Assessment* (*PCA*), a research developed instrument based on college students' common misconceptions of functions (Carlson, Oehrtman, & Engelke, 2010) after completing four years of college preparatory mathematics and AP Calculus.

Theoretical Framework

Precalculus Concept Assessment

The *PCA* is a 25-item multiple choice exam that helps researchers and instructors learn what students think and understand about the foundational concepts of precalculus and beginning calculus (see Carlson et al., 2010, for released items). The *PCA* was developed based on research with collegiate level mathematics classes, and was piloted and revised over the past 15 years.

The *PCA* is based on a taxonomy developed to determine student's understandings and reasoning of foundational concepts learned during a precalculus course (Carlson et al., 2010).

Although the *PCA* was not created to be used as a placement exam for Calculus, Carlson et al. (2010) reported that 77% of college students who scored a 13 or higher on the *PCA* passed a first semester calculus course with a C or better. The correlation coefficient for college student *PCA* scores and their calculus grades was 0.47.

The *PCA* was validated with college students who enroll in College Algebra and Precalculus. The study reported in this paper provides a different sample of students, those who are in high school and enrolled in Advanced Placement (AP) Calculus. Students took the *ACT, PCA* and the AP Calculus AB or BC exams during their high school years. Although one might assume that precalculus at the college level is equivalent to precalculus at the high school level, the *PCA* had not been used to analyze student thinking at the high school level.

Content of AP Calculus Courses and Exams

The AP Calculus AB course focuses on limits, derivatives, and an introduction to integrals, which is typically taught in a first semester calculus course in college. The AP Calculus BC course focuses on the topics studied in AB; however, more depth is given to integration and students are introduced to sequences and series as well as parametric and polar functions, which is typically taught in a two semester calculus sequence in college. The AP Calculus exams award students with a score of one to five inclusive with five being the highest score. On each of the AB and BC exams, those students who score four or five pass the exam, and may use their scores to receive college credit for Calculus courses when they enter college. It is evident that a strong foundation of precalculus is absolutely essential for success in Calculus; therefore the *PCA* can be a valuable tool for identifying the students' weaknesses in precalculus if administered to students prior to entering Calculus.

Content of ACT Mathematics Exam

The *ACT mathematics* exam is a 60-question, 60-minute test designed to measure the mathematical skills students have typically acquired in courses taken by the end of 11^{th} grade (ACT, 2011). Students receive an overall score between one and 36 inclusive and three sub-scores based on six content areas: pre-algebra (23%), elementary algebra (17%), intermediate algebra (15%), coordinate geometry (15%), plane geometry (23%) and trigonometry (7%). All of these topics are highly correlated with the content of the *PCA* and if used with PCA, can be employed as a diagnostic tool for predicting how students are likely to succeed in the AP Calculus system.

Regression Analysis

In statistics, regression analysis includes techniques for modeling and analysis of several variables, when attention is focused on the relationship between a dependent variable and one or more independent variables. More specifically, regression analysis helps us understand how the typical value of the dependent variable changes when any of the independent variables is varied, while the other independent variables remain fixed. Usually, regression analysis estimates the conditional expected value of the dependent variable given the independent variables (i.e. the mean (average) value of the dependent variable when independent variables are kept fixed). Regression analysis is widely used for estimation and prediction. It is also used to explore and comprehend the causal relationships that exist among the independent variables in relation to the dependent variable. In this study, regression analysis is the primary means of inquiry in order to explore the relationships between the AP Calculus AB and BC exam scores, *PCA* results and *ACT mathematics* test scores.

Research Questions

In light of the scope of the *PCA*, the *ACT mathematics* test as well as the AP Calculus AB and BC exams, this study specifically seeks to answer the following research questions: (1) How are high school students' *PCA* scores and AP Calculus AB or BC scores related? (2) Can students' *PCA* scores be used to predict their performance on the AP Calculus AB or BC exams? (3) Can the prediction be improved when the *ACT* scores are available?

Methodology

In this study, the 16 different regression schemas are built upon three regression based models, namely, Multiple Linear Regression Model, Multinomial Logistic Regression Model and Cumulative Odds (CO) – Ordinal Regression Model.

Regression Models

Regression models were used in this study to predict students' AP Calculus AB or BC scores (i.e. an integer between 1 and 5 inclusive); in other words, students' AP Calculus AB or BC scores were the dependent variables. The independent variables were student responses to the 25 individual questions in the *PCA*, each being a 1 (that represents a correct answer) or a 0 (that represents an incorrect answer); these will be referred to as *PCA results* in the rest of the paper. In some of the regression models students' *ACT mathematics* scores were used as another independent variable.

The Multiple linear regression model. This model assumes that a linear relation exists between the dependent and the independent variables where the random errors are assumed to be independent and normally distributed random variables with zero mean and constant standard deviation, (i.e., assumptions of normality, linearity, and homogeneity of variance are met). The dependent variable is students' AP Calculus AB or BC score and whereas the independent variables are the responses to the 25 *PCA* questions with or without the *ACT mathematics* scores as; thus, depending on the regression model, there are 25 (without the *ACT mathematics* score) or 26 (with the *ACT mathematics* score) independent variables.

The multinomial logistic regression model. Multinomial logistic regression (Kutner et al., 2005) does not require any assumptions of normality, linearity, and homogeneity of variance for the independent variables. Because this regression model is less stringent it is often preferred to discriminant analysis when the data does not satisfy these assumptions.

Suppose the dependent variable has M nominal (unordered) categories. One value of the dependent variable is chosen as the reference category and the probability of membership in each of the other categories is compared to the probability of membership in the reference category. For the dependent variable with M categories, this requires the calculation of $M – 1$ equations, one for each category relative to the reference category, in order to describe the relationship between the dependent and the independent variables. Please note that multinomial logistic regression model ignores the ordinal nature that might exist within the levels of the dependent variable and treats each category in a similar manner.

The cumulative odds (CO) – ordinal logistic regression model. The CO – ordinal regression model (Kutner et al., 2005) calculates the probability of being at or below category m of an ordinal dependent variable with M categories. Ordinal logistic regression is different from multinomial logistic regression in that it takes into account the ordinal nature inherent within the levels of the dependent variable, which might be useful in some cases.

For the two logistic regression models (multinomial or CO – ordinal) each of the AP Calculus AB or BC scores had five levels (i.e. an integer between one and five inclusive). For multinomial the logistic regression model, the last level (AP Calculus AB or BC score being equal to 5) was selected as the reference category.

The dependent variables were again the *PCA* results used as categorical variables (factors). The *ACT mathematics* test scores could be used as both categorical and ordinal variables. When the *ACT mathematics* test scores were used as categorical variables (factors), each level inherent within the score was a separate independent variable; when they were used as ordinal variables (covariates), they constituted a single independent variable.

Participants

At the end of a school year, 193 high school students from two high schools in a mid-western town were administered the *PCA* to assess their understandings and reasoning abilities prior to entering AP Calculus (Teuscher & Reys, in press). Of the 193 students who took the *PCA* and enrolled in AP Calculus AB or BC the following year, 143 students took the AP Calculus exam at the end of the school year; 80 of these students were enrolled in the AP Calculus AB course while the remaining 63 were enrolled in AP Calculus BC course.

The AP Calculus exam is scored and then students are given a grade of one to five. Typically students who receive a four or five grade receive college credit for at least one semester of calculus. Those students who take the AP Calculus BC exam receive a BC grade and an AB sub-grade. It is possible that a student who takes the BC exam many not receive a four or five on the BC exam, but receives a four or five on the AB portion of the test, which can be interpreted as having passed the calculus AB exam, but not the BC exam.

Prediction Process

The models that used the *PCA* results to predict the AP Calculus AB of BC scores are based on the three regression models (Multiple Linear Regression, Multinomial Logistic regression and the CO – Ordinal Logistic Regression). The predictors in all three regression models were the actual results of each of the 25 questions in the *PCA* test, (i.e. each test question was associated with one of two categorical values, 1 if it was answered correctly and 0 if it was answered incorrectly).

The *ACT mathematics* score can theoretically take ordinal values between 1 and 36 inclusive (ACT, 2011). In statistics, higher level variables can always be downgraded to lower level ones, such that, a metric scale variable can be downgraded to an ordinal or a nominal variable; this process sometimes requires defining categories within the data and/or creating discrete values based on the continuous scale variables (Kent, 2001). The *ACT mathematics* score already takes discrete values, which is reason alone why it can be treated to be ordinal or nominal as well. While it is theoretically possible for a student to score between one and 36 inclusive (ACT, 2011), this is usually not the case in practice; for instance the scores of a group of high school students attending the same school may exhibit a certain pattern. The scores of the group of students subject to our analyses were between 19 and 34 and none of the students scored 22. This is another justification for the fact that *ACT mathematics* score can be treated as an ordinal or categorical variable.

Dependent Variable	Independent Variable(s)
AP Calculus	*PCA*
AP Calculus	*PCA* and Actual *ACT mathematics* scores

Table 1. The variables used for the three linear regression models to predict students' *ACT mathematics* and AP Calculus (AB or BC) scores.

Two different linear regression models used students' *PCA* results with or without the *ACT mathematics* scores to predict students' AP Calculus AB or BC scores; when the *ACT* *mathematics* scores were used, they were treated as ordinal metric variables. The variables used for the linear regression models used in this study are summarized in Table 1 above.

The Logistic Regression models (Multinomial and Ordinal) predict a categorical or an ordinal dependent variable using categorical predictors as factors with or without ordinal variables as covariates. These two models were employed to predict the AP Calculus AB or BC scores separately using students' *PCA* results with or without the actual *ACT mathematics* scores; the ACT mathematics scores were used as categorical variables (predictors) or as ordinal variables (covariates). The logistic regression models used in this study are summarized in Table 2.

Model Specification	Dependent Variable	Independent Variable(s)	
		Categorical Variables (Factors)	Ordinal Variables (Covariates)
A	AP Calculus AB or BC Score	*PCA*	
B	AP Calculus AB or BC Score	*PCA* Score and Actual *ACT mathematics* Scores	
C	AP Calculus AB or BC Score	*PCA* Score	Actual *ACT mathematics* Scores

Table 2. The logistic regression models (multinomial or CO-ordinal) used to predict students' AP Calculus AB or BC scores.

Results

As it might be expected, students enrolled in AP Calculus BC scored higher (mean of 17.51 and standard deviation of 3.18) than students in AP Calculus AB (mean of 15.69 and standard deviation of 3.21) on the *PCA* (where the total score possible was 25) prior to entering AP Calculus. Eighty-one percent of the students in this study who took one of the AP Calculus exams pass it with a four or five.

A positive Pearson correlation existed between students' *PCA* scores and the AP Calculus exam grades and it was statistically significant (r = 0.40, p = 0.000). This can be interpreted as students who receive a high *PCA* score are likely to receive a high AP Calculus exam grade. Then again, a positive Pearson correlation existed between students' *PCA* scores and the *ACT mathematics* test scores and it was statistically significant (r = 0.28, p = 0.02). This can be interpreted as students who receive a high *PCA* score and/or a high *ACT mathematics* test score are likely to receive a high AP Calculus exam grade. The AP Calculus AB scores were available for 80 students; the mean score was 4.00 and the standard deviation was 0.95. Whereas the AP Calculus BC scores were available for 63 students; the mean score was 4.13 and the standard deviation was 0.96.

The AP Calculus AB scores were predicted using the two multiple linear regression models given in Table 1 and the Pearson correlations were calculated between the actual and predicted values. The actual values of students' *ACT mathematics* scores were also used to assess whether or not their inclusion while predicting the AP Calculus AB and BC scores would in fact improve the prediction. The results indicate strong positive correlations and are summarized in Table 3 which can be interpreted as follows: AP Calculus AB scores can be predicted with 48% ($100 \times 0.69^2 = 48\%$) accuracy when using students *PCA* results alone or 75% ($100 \times 0.87^2 = 75\%$) accuracy when using students' *PCA* results along with their *ACT mathematics* test scores.

Model	AP Calculus AB Scores Predicted from the *PCA* Scores	AP Calculus AB Scores Predicted from the *PCA* and Actual *ACT mathematics* Test Scores
Pearson Correlation	0.69	0.87
N	80	48
M (SD)	3.74 (0.83)	3.84 (0.91)

Table 3. AP Calculus AB test scores predicted using the multiple linear regression models.

The AP Calculus AB scores were predicted using the three distinct model specifications for the multinomial logistic regression models given in Table 2 and the Pearson correlations were calculated between the actual and predicted values. The results indicate strong positive correlations and are summarized in Table 4. Model specifications B and C yielded perfect correlations with 100% accuracy in predicting the AP Calculus AB test scores. The results summarized in Table 4 can be interpreted as follows: AP Calculus AB scores can be predicted with 91% ($100 \times 0.95^2 = 91\%$) accuracy when using students' *PCA* results alone or 100% ($100 \times 1^2 = 100\%$) accuracy when using students' *PCA* results along with their *ACT mathematics* scores using the *ACT mathematics* scores as factors or covariates depending on the model.

Model Specification	A	B	C
Pearson Correlation	0.95	1.00	1.00
N	80	48	48
M (SD)	3.80 (0.99)	3.99 (0.99)	3.97 (0.95)

Table 4. AP Calculus AB test scores predicted using the multinomial logistic regression models.

The AP Calculus AB scores were also predicted using the three distinct model specifications for the CO – ordinal logistic regression models given in Table 2 and the Pearson correlations were calculated between the actual and predicted values. The results indicate strong positive correlations and are summarized in Table 5. Model specifications B yielded a perfect correlation with 100% accuracy in predicting the AP Calculus AB test scores. The results summarized in Table 5 can be interpreted as follows: AP Calculus AB scores can be predicted with 40% ($100 \times 0.63^2 = 40\%$) accuracy using the *PCA* results alone; with 100% ($100 \times 1^2 = 100\%$) accuracy using both the *PCA* results and *ACT mathematics* scores as factors or with 70% ($100 \times 0.84^2 = 70\%$) accuracy using *PCA* results along with the *ACT mathematics* scores as covariates.

Model Specification	A	B	C
Pearson Correlation	0.63	1.00	0.84
N	80	48	48
M (SD)	3.76 (1.07)	3.97 (1.06)	3.94 (1.01)

Table 5. AP Calculus AB test scores predicted using the CO – ordinal regression models.

The AP Calculus BC scores were predicted using the two multiple linear regression models given in Table 1 and the Pearson correlations were calculated between the actual and predicted values. The results indicate strong positive correlations and are summarized in Table 6. The results can be interpreted as follows: The AP Calculus BC scores can be predicted with 57% ($100 \times 0.75^2 = 57\%$) accuracy using the *PCA* results alone; or 95% ($100 \times 0.97^2 = 95\%$) accuracy using the *PCA* results along with the *ACT* mathematics test scores.

Model	AP Calculus AB scores predicted from the *PCA* scores	AP Calculus AB scores predicted from the *PCA* and the actual *ACT mathematics* scores
Pearson Correlation	0.75	0.97
N	63	25
M (SD)	4.15 (0.71)	3.92 (0.92)

Table 6. AP Calculus BC test scores predicted using the multiple linear regression models.

The AP Calculus BC scores were predicted using the three distinct model specifications for the multinomial logistic regression models given in Table 2 and the Pearson correlations were calculated between the actual and predicted values. The results indicate strong positive correlations and are summarized in Table 7. Model specifications B and C yielded perfect correlations with 100% accuracy in predicting the AP Calculus BC test scores. The results can be interpreted as follows: AP Calculus BC scores can be predicted with 69% ($100 \times 0.83^2 = 69\%$) accuracy using the *PCA* results alone; or 100% ($100 \times 1^2 = 100\%$) accuracy using the *PCA* results along with the *ACT mathematics* scores which are used as factors or covariates depending on the model.

Model Specification	A	B	C
Pearson Correlation	0.83	1.00	1.00
N	63	25	25
M (SD)	4.10 (0.98)	3.89 (0.93)	3.89 (0.93)

Table 7. AP Calculus BC test scores predicted using the multinomial logistic regression models.

The AP Calculus BC scores were predicted using the three distinct model specifications for the CO – ordinal logistic regression models given in Table 2 and the Pearson correlations were calculated between the actual and predicted values. The results indicate strong positive correlations and are summarized in Table 8. Model specifications B and C yielded perfect correlations with 100% accuracy in predicting the AP Calculus BC test scores. The results can be interpreted as follows: The AP Calculus BC scores can be predicted with 49% ($100 \times 0.70^2 = 49\%$) accuracy using the *PCA* results alone; or 100% ($100 \times 1^2 = 100\%$) accuracy using the *PCA* results along with the *ACT mathematics* scores as factors or covariates depending on the model.

Model Specification	A	B	C
Pearson Correlation	0.70	1.00	1.00
N	63	25	25
M (SD)	4.23 (0.94)	3.89 (0.93)	3.89 (0.93)

Table 8. AP Calculus BC test scores predicted using the CO – ordinal regression models.

Please note that each of the 16 regression models summarized above as well as the Pearson correlation values reported were statistically significant at the 0.01 level.

Discussion

Assessments are the standard for which teacher and institutions judge students' knowledge. With the *No Child Left Behind ACT of 2001* (NCLB, 2001) K-12 students are taking assessments each year to demonstrate adequate yearly progress. However, the majority of these exams were not developed with the intention of providing students or teachers with feedback on deficiencies in student's knowledge. The college mathematics placement exams were also not developed with the end goal of assessing relevant and connected concepts that are foundational for calculus.

The results of this study provide evidence that the *PCA* may be an exam that could be used for multiple settings across high schools and colleges in the US. The *PCA* was found to be significantly correlated with the AP Calculus AB and BC exams and correspondingly the *PCA* scores was a statistically significant predictor of the scores on these exams. The results verify that multiple linear, multinomial logistic and CO-ordinal logistic regression models can successfully be used in one or more of these predictions. As for the generalizability of the results obtained, the mean and standard deviation values calculated for each of the actual and predicted AP Calculus AB or BC scores were very close meaning that the results were indeed generalizable.

While predicting the AP Calculus AB and BC scores, using the actual *ACT mathematics* scores as factors or covariates improved the results of the prediction; particularly using the actual *ACT mathematics* scores as ordinal variables (or factors) while performing logistic regression yielded very strong positive and sometimes perfect correlations between the actual and the predicted values.

These findings are consistent with research reported by Carlson et al. (2010) who found that the *PCA* was a predictor of college students ability to receive a passing grade in calculus at the college level. The *PCA* was specifically created to provide feedback to instructors on what their students understand and do not understand about functions. Instructors could use the results from the *PCA* to determine what prior knowledge or more importantly what misconceptions students have when entering a course that may cause them to not understand and grasp the new material they encounter. The *PCA* could also be used to provide instructors with diagnostic feedback on the specific precalculus topics that students did not understand during their precalculus classes and then make modifications to their curriculum for future classes.

A considerable amount of time and taxpayer money is spent every year on students who retake calculus in college because they are not able to pass the college mathematics placement test. There are also a vast number of students who drop out of calculus in college and feel the urge to change their majors simply because of having the prejudice that they are unable to succeed in mathematics; in fact this is not a new problem and it has not been solved as of yet (Ma et.al., 1999). Thus, an early detection system could be part of the solution and be of immense assistance to students, parents and teachers to take the necessary measures early (i.e. when the students are still in high school). This is why a powerful tool like the *PCA* can be used to identify students who need to spend more time on precalculus and are likely to have a hard time in AP Calculus class or college level calculus, by predicting their AP Calculus AB or BC test scores even before they enter the AP Calculus system.

However, it must be noted that the timing of the *PCA* test is an important factor to produce the results which will enable the prediction of the scores on the AP Calculus AB or BC tests. The *PCA* test should ideally be administered immediately after completing the precalculus content courses prior to the students starting the AP Calculus AB or BC courses.

In closing, it is important to realize that without a purpose, assessments will become something that students *do* and not something that is *useful* to them or instructors. The *PCA* is a practical focused examination that can provide students and instructors with important feedback to improve students' understandings of the common mathematical topics that are necessary for students to be successful in calculus.

MAKING THE FAMILIAR STRANGE: AN ANALYSIS OF LANGUAGE IN POSTSECONDARY CALCULUS TEXTBOOKS THEN AND NOW

Veda Abu-Bakare
Simon Fraser University
vabubabaka@sfu.ca

Three calculus textbooks covering a span of about 40 years were examined to determine whether and how the language used has changed given the Calculus reform movement and the impetus to make mathematics accessible to all. Placed in a discourse analytic framework using Halliday's (1978) theory of functional components, ideational, interpersonal and textual, and using the exposition of the concept of a function as a unit of comparison, the study showed that the functions and forms of language are integral indicators of the author's view of mathematics and the reader's extent of agency and construction of identity.

In the late 1980s, the Calculus Consortium at Harvard (CCH) comprised of eight institutions including universities, a high-school, and a community college, was funded by the National Science Foundation to redesign the Calculus curriculum with a view to making Calculus more applied, relevant, and accessible. The intent was to re/think and re/present the content so as to focus on real-world applications, to emphasize concepts and graphical representations, and to take advantage of the increasingly sophisticated technology. This initiative has been extensively embraced leading to the calculus reform movement. As a result, Calculus is now mostly presented in a manner radically different from the traditional approach which relied heavily on abstraction, formal notation and symbolism, and algebraic conventions. Besides the 'regular' Calculus courses, Calculus courses and materials have been developed for specific disciplines (such as Biology and Economics) and for different modes of delivery (such as Calculus with Computer Explorations).

The goal of this research is to see whether and how calculus textbooks designed for the postsecondary level in 'regular' Calculus courses have changed over the years with respect to the language used in the exposition and by inference, the view of mathematics manifested. One concept, that of a function and in particular its definition, is chosen and used to trace the dimensions of the language over the years and the consequent shifts in the view and presentation of mathematics in calculus textbooks. The questions that arise for me are: Has the language of calculus textbooks changed over time and if so, in what ways? From the language, how are the authors' views of mathematics characterized and how have they changed over time? Has the language changed from one that is exclusive (mathematics as an elite subject with an elite community) to one that is inclusive and accessible to all?

The three textbooks I have chosen are *Calculus* by Spivak (1967), *The Calculus of a Single Variable with Analytic Geometry*, 5th edition by Leithold (1986), and *Single Variable Calculus: Early Transcendentals*, 5th edition by Stewart (2003). Spivak and Leithold were both Mathematics Professors from American universities (Brandeis and Pepperdine, respectively) writing for an American audience while Stewart is an Emeritus Professor in Mathematics at a Canadian university (McMaster) writing for a North-American audience. Each of these textbooks was well-known and well-used in its time. I chose the first two because they were the ones that I

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

still have after the many moves in my life and the third because it is one that I use in my teaching at this time.

Textbooks may be studied subjectively to describe the interaction between the student and the written material or to describe teachers' use of textbooks and the subsequent effect on the teacher (Remillard et al, 2009). However, following Herbel-Eisenmann (2007), I seek to examine the '*voice'* of calculus textbooks over the years as 'objectively given structure' (emphasis in the original, p.396). This examination will be placed in a discourse analytic framework which attends to the aspects of text relating to language, voice, agency and identity. In particular, linguistic markers such as the use of pronouns, imperatives and modality will be traced as a means of addressing the above questions.

Analytic Framework

Starting with the ideas in Pimm (1987)'s *Speaking Mathematically: Communication in Mathematics Classrooms*, discourse analysis of text (written and oral) has now acquired a firm footing in Mathematics Education. Discourse analysis seeks to investigate how language frames the ongoing conversation about the origins and constructions and knowledge and their relation to action and empowerment. Critical discourse analysis recognizes the power relations in this activity and seeks to make space for alternate epistemologies and ideologies. In Mathematics Education, discourse analysis and critical discourse analysis have been used to study written student investigations (Morgan, 1998), silence and voice in mathematics classroom discourse (Wagner, 2007), the 'voice' of a mathematics textbook (Herbel-Eisenmann, 2007), and the pragmatics (the ways in which context communicates meaning) of mathematical discourse (Rowland, 2000).

Language has been increasingly seen as an important issue relating to mathematics teaching and learning. Rowland (2000) emphasizes two principles in studying language: the linguistic principle ('language as means of accessing thought') and the deictic principle (language as a means of communication and a 'code to express and point to concepts, meanings and attitudes') (p. 2). In his *Language as a Social Semiotic*, Halliday (1978) identifies three functional components or functions of language, the ideational, the interpersonal, and the textual, from which meaning is apprehended.

The ideational functional component of the text answers the questions: What is the view of mathematics as presented in the text? How is the subject of mathematics envisioned in the mind of the author of the text and in what style is it rendered? The ideational function describes the nature of the subject matter from the ideological and epistemological stance of the author. It is 'the component through which the language encodes the cultural experience and the speaker encodes his own individual experience as member of the culture' (Halliday, 1978, p. 112). It also names the objects, concepts, and processes involved in mathematical activity and indicates agency on the part of the author and reader. The ideational function is composed of the experiential function (dealing with transitivity and agency) and the logical function (relating to continuity and modes of argument).

The interpersonal functional component describes the social and personal roles and relationships among the authors and readers and the ways in which the readers interact with the written text and the textbook itself as a whole. Evidence of this function is discerned by considering the use of personal pronouns (first person, I/we/us/our, and second person, you/your), imperatives, and modality. The interpersonal function is the 'participatory function of language, language as doing something' (Halliday, 1978, p. 112).

The textual functional component describes the content matter or the mathematics presented in the text, the theme and modes of reasoning, the arguments and their forms, and the narratives of mathematical activity. Halliday describes it as 'the component which provides the texture: that which makes the difference between language that is suspended in vacuo and language that is operational in a context of the situation' (pp.112-113). Evidence of the textual function is seen in the cohesive devices the text uses to preserve consistency and continuity.

Halliday also introduces three concepts which shed more light on these three functional components, namely, field, tenor, and mode, respectively. The field refers to what is going on in the context of the situation and what the participants are doing, the tenor to the roles of the author and the reader and how they stand in relation to one another, and the mode to the channel or wavelength that the author has chosen to use depending on 'what function the language is being made to serve in the context of the situation' (p. 222).

I will examine each of the textbooks with respect to these three functional components and compare and contrast them as to the "voice" that emerges, the extent of agency, and the construction of the identity of the reader by the text.

Method

The data consists of the pages from the three Calculus textbooks that cover the exposition of the concept of a function. I chose this concept because it is fundamental and key to the subject. By exposition, I considered the preliminary introductory commentary and the definition (or definitions) of a function. In each textbook, there were many more pages devoted to the important classes of functions such as polynomial, exponential, logarithmic, and trigonometric functions, but I chose to limit the analysis to only those pages relating to development of the concept and the definition of a function.

I mined the relevant pages (about 20 pages from each textbook) carefully with respect to the markers for the three functions as articulated by Halliday and elaborated by Morgan (1996). I paid close attention to the use of personal pronouns, imperatives, and modal auxiliary verbs. I also considered the use of questions and conditionals, if, if…then, given, and given that, as evidence of forms of reasoning and modes of argument.

Findings and Discussion

The results of the comparison of the textbooks across markers for the functional components of language with respect to the concept of a function are given in Table 1.

	Spivak (1967)	Leithold (1986)	Stewart (2003)
Pronouns - 1st person	we/us/our 32 instances	we/us 5 instances	we/us 24 instances
Pronouns – 2nd person	you 9 instances	None	you 3 instances
Imperatives Inclusive	let's 1 instance	call, compare, let, note, observe, recall 6 instances	consider, determine, let, notice, remember 7 instances
Imperatives Exclusive	None	find, read 4 instances	draw, find, sketch, use 6 instances
Modal verbs	may 2 instances	None	None
Questions	2	None	1

Conditionals	if 6 instances if … then 10 instances	given 3 instances given that 2 instances	if 3 instances if … then 4 instances

Table 1. Comparison across Markers for the Functional Components.

The Interpersonal Functional Component

The most easily-detected functional component of language is the interpersonal which describes the roles and relationships of the author and the readers. This component can be discerned from the incidence of personal pronouns, imperatives, and expressions of modality.

The most striking occurrence is that of 32 instances of first-person pronouns in Spivak as compared with five in Leithold and 23 in Stewart. In Spivak, there were 29 uses of we, two of us and one of our. My reading of this is that Spivak views the reader as someone who is part of the community of people doing or studying mathematics. From the opening paragraph in his liberal use of we and us, Spivak sets the tone of including the reader in his deliberations. He concludes his opening paragraph with 'Let us therefore begin with the following:' (p. 37). An alternative reading of we is given by Pimm (1987) who questions the we that authors use and wonders how he personally is implicated in the proceedings as to responsibility for what may ensue. Another possible reading is that the use of we, us, and our suggests a more general form indicative of the register of mathematicians, especially in written mathematics.

In comparison to this substantial use of first-person pronouns, the five occurrences of we in Leithold read clinically as in 'we see that' or 'we observe that'. There is an implied us in the following sentence from Leithold: 'In Definition 0.5.1 the restriction that no two distinct ordered pairs can have the same first number assures that y is unique for a specific value of x' (p. 45), for whom does the restriction assure, if not us, the readers?

In keeping with Spivak's view of the reader as a thinking and feeling partner in the endeavour, there are nine instances of you as he recognizes the presence of the reader, such as 'It will therefore probably not surprise you to learn that …' (p. 37) and 'you may feel that we have also reached the point where…' (p. 45). However, Spivak does write at one point: 'You should have little difficulty checking the assertions that…' (p. 39), which is an assumption that may leave the reader a little frustrated if some difficulty is encountered. Later, he redeems himself with his regard for the reader in 'If the expression $f(s(a))$ looks unreasonable to you, then you are forgetting that $s(a)$ is a number like any other number, so that $f(s(a))$ makes sense' (p. 40). This is an early indication of affect in mathematics learning, in recognizing the role of emotions and feelings. There are no instances of address to the reader in Leithold while Stewart has three: 'as you can see', 'You can see that…', and 'when you turn on a hot-water faucet…'.

The use of personal pronouns indicates the presence or absence of humans in the activity and the implied distance and degree of formal relationship between the author and the reader (Morgan, 1996). Spivak and Leithold are at opposite ends of the continuum in this regard. Spivak even employs the construction, 'Lest you become too apprehensive about…' and 'let us hasten to point out that…' which is by far the greatest consideration an author can give to a reader. Here again Spivak is demonstrating his recognition of the phenomenon of affect, despite his quaint sentence construction. Leithold deploys his words in a detached 'scientific' manner, the very opposite of the kind of writing that Burton and Morgan (2000) exhort mathematicians to adopt.

The frequency of imperatives in a text indicates the degree to which the author wishes to draw the reader's attention to a point in the text (note that, observe that), to encourage the reader to reflect (consider, compare, recall, remember), or to give a simple command (find, sketch, use). Both Leithold and Stewart use a similar number of imperatives that indicate the usual textbook framing (consider, notice, observe, recall) and that signal the power of the author (determine, evaluate, find, sketch, use) to tell the reader what to do. The former are examples of inclusive imperatives that characterize the reader as 'thinker' while the latter are examples of exclusive imperatives that characterize the reader as 'scribbler' (Rotman, 1988). The use of imperatives shapes the relationship between author and reader and serves to construct the reader as a potential member of a community (Morgan, 1996). It is note-worthy that Spivak does not use any of these imperatives but still manages by his use of personal pronouns to convey a sense of introducing the reader to and including the reader in the community of mathematicians and the activity that mathematicians undertake.

The imperative 'let' occupies a special place in mathematics (as is commonly found in arguments and proofs, for example, let □ be…). Spivak uses it once in 'Let us therefore begin with…' (p. 39), which is more of an invitation rather than a call for consideration. Leithold uses the construction, let □ be…, three times. There are no instances of let in Stewart in the pages under consideration but there is a variety of other imperatives that are roughly equally inclusive and exclusive (Table 1).

Modality, as a feature of language, enables authors and speakers to express their feelings, values, attitudes, and judgments about the propositions in their texts. Halliday (1978) expresses a preference for the term, modulation, rather than modality in that the text is modified or nuanced in some way. Demonstrations of modality include modal auxiliary verbs such as 'may' and 'can', adverbs relating to the uncertain state of knowledge such as 'possibly' and 'maybe', the use of moods and tenses, and the use of hedges (Rowland, 2000, p. 65). For these three textbooks there was little or no evidence of modality. There were two instances of 'may' in Spivak ('You may feel that we have also reached…' and 'Two consolations may be offered', p. 45). These have nothing to do with the mathematics involved but indicate concern for and offer solace to the reader. Leithold and Stewart offer no suggestion that that there is any uncertainty related to mathematical activity and by their lack of use of modality, indicate a view of mathematics that strongly holds to an absolute, ideal perspective.

As seen from these markers for the interpersonal functional component, the tenor of the language in the three textbooks is marked differently. Leithold and Spivak are diametrically opposite in the use of the first and second person pronouns and imperatives in engaging and addressing the reader with Stewart striking a moderate note in this regard.

The Textual Functional Component

All three authors use the mode of discourse characterized by exposition (evident of the raison d'être of the textbook) in laying out a clear and concrete treatment of the subject matter. Questions as evidence of a conversational or dialogic style of exposition were barely used; there were two questions in Spivak, none in Leithold and one in Stewart. The one instance in Stewart is a perfect example of the question-and-answer cohesive form: 'The graph of a function is a curve in the xy-plane. But the question arises: Which curves in the xy-plane are graphs of functions? This is answered by …' (p. 17).

One instance of a question in Spivak is a particularly engaging example of language that recognizes and cements the roles and relationships in the text: 'By what criterion, you may feel

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

impelled to ask, can such functions, especially a monstrosity like (12), be considered simple?' This question manages to capture pronoun use, affect, and modality, all in one fell swoop. With respect to forms of reasoning, there are similar numbers of instances of conditionals in all three textbooks such as if and if…then which are widely used in mathematical arguments. Leithold has 5 instances of given and given that but these are not used as conditionals in an argument. Instead they are used in examples such as, Given that $\square$ and $\square$ are defined by $\square$ and $\square$. The current usage is more informal: 'Suppose that …' which, as a shortened form of 'Let us suppose that…', is more of an invitation.

The Ideational Functional Component

The ideational functional component in each of the three textbooks is very nearly identical in that the authors' content and meaning are very similar. Each author is interested in communicating the content of the concept of a function. Further, each author conveys the weightiness of the subject matter and the experience of being part of the culture of being mathematicians and doing mathematics. Each is writing of the objects and relations that are under consideration when introducing and discussing the concept of a function. By the degree of use of the linguistic markers analyzed above, each encodes in the text his individual vision of mathematics. The view of mathematics evinced in all three is fixed, absolute, and formal.

Besides the content, the ideational component, in describing which actors carry out which processes, speaks to the concept of agency as it is invited or suppressed. Morgan (1996) elaborates on the use of nominalization in order to suppress or mask agency. Clear examples of suppression of agency occur in Leithold: 'Equation (1) defines a function' and 'This equation gives the rule by which …' (p. 45). There are no similar constructions in Spivak or Stewart.

In summary, the three textbooks are similar in their theme and message but differ considerably in the interpersonal component with Stewart capturing a moderate position between what may be considered the extremes of linguistic markers by Leithold and Spivak.

Conclusion

The language of mathematics is often seen as foreign with its own lexicon, grammar, and modes of argument. More than being able to negotiate the language, students of mathematics must become fluent in it in order to be successful. Bakhtin declares that '[e]ach text presupposes a generally understood (that is, conventional within a given collective) system of signs, a language (if only the language of art)' (1953/1986, p. 105). Hence the mathematics textbook, as text, has a conventional system of signs which is part of a language that must be understood in order to be able to participate in the community involved in mathematical activity.

While there is a core of conventions that must be observed in written mathematics such as the infallibility of written mathematics, the analysis above shows that the forms of language used encode the ideological stance of the author. Spivak wrote at a time when mathematics in textbooks was more theoretical and formal. While he is careful to draw the reader in and attend to how the reader is managing, he plots a watchful thoughtful course through the content. For Leithold, mathematics is austere and closed. His language is methodical and authoritative. Stewart begins with an applied focus with multiple representations of functions from the real world. His language is readable and brisk with many examples, sidebars and cautionary notes. Further, the linguistic devices, such as nominalization and cohesive forms, indicate the extent of agency afforded the reader and the construction of the identity of the reader as a potential member of the community of mathematicians.

The differences in language in a textbook account for much of the reader's regard for the textbook and for the teacher's ability to mediate the textbook with her students. In this paper I have teased out the subconscious linguistic markings in the text and have shown that there is more to the text than meets the eye; that what we have taken as familiar is indeed strange, and that the language of mathematics does reveal beliefs and ideas about mathematics which we adopt and perpetuate without realizing the implications and consequences. This analysis suggests that it behooves us as teachers to look again at language and its signs and to re/examine our textbook choices, while attending to the functions and forms of language that subtly maintain hegemonic practices in the teaching and learning of mathematics.

MIDDLE LEVEL TEACHERS' PERCEPTIONS OF WHOLE-CLASS MATHEMATICAL DISCOURSE

Cory A. Bennett
Idaho State University
dr.corybennett@gmail.com

Whole-class discourse is an important component in developing relational understanding in mathematics. Teachers' perceptions of this instructional and assessment strategy can greatly influence and affect its use, implementation, and overall success. However, facilitating whole-class discourse with adolescents can be difficult as they are often reluctant to participate in situations that are potentially embarrassing. This study identified strategies that middle level mathematics teachers used to promote whole-class discourse and also compared teachers' perceptions with their actual classroom practice. Several areas of concern were identified due to the discrepancies between teachers' perceptions and their actual practice.

The learning experiences students encounter within schools is fundamental to their academic achievement and attainment (Marzano, 2004). However, the selection, nature, and design of these experiences are largely left up to the teacher which means that teacher preferences in the design and implementation of these experiences will often determine how the curriculum content is presented to the students. Learning experiences that also include whole-class discourse (WCD) are important for middle level students as students' understanding of content is strengthened through communication (Gose, 2009; National Council of Teachers of Mathematics [NCTM], 2000; Pugalee, 2001; Roberts & Billings, 2009). Yet, generating mathematical discourse amongst adolescents can be especially challenging, particularly within a whole-class setting as social acceptance by adolescents' peers is paramount; they wish to avoid embarrassment or appearing incompetent (Van Hoose, Strahan, & L'Esperance, 2001).

The purpose of this qualitative multi-phase case study was to better understand teachers' perceptions towards WCD as it relates to the facilitation of WCD, the utility of WCD as an instructional strategy to support all students in the learning of mathematics, as well as to better understand the methods that teachers tend to implement to support the facilitation of WCD. By understanding teachers' perceptions of WCD, more informed decisions on how to support teachers within the classroom and improve effective instructional and assessment strategies can be further developed. Furthermore, knowing how teachers view their practice today can help educational leaders redefine and shape future classrooms.

Research Questions

The research question that guided this study focused on teachers perceptions of WCD in relation to their actual classroom practices. Specifically, in what ways were middle-level teachers' perceptions towards whole-class mathematical discourse, as a means of supporting all students in learning mathematics, aligned with their actual classroom practice?

Relevance to Current Literature

Mathematical discourse is certainly not a new phenomenon and there is an abundance of literature that supports various aspects of WCD and the benefits it provides students and teachers (Falle, 2004; Hoffman, Breyfogle, & Dressler, 2009; Huang, Normandia, & Greer, 2005; Kuhn, 2005; Larsen & Bartlo, 2009; Mercer, 2008; NCTM, 2000; Roberts & Billings, 2009; Stein, M. K., Engle, R. A., Smith, M. A., & Hughes, E. K., 2008). Two of these benefits support students' higher level thinking and provide teachers with insightful and timely assessment opportunities.

Helping students develop as creative and complex thinkers is important in any discipline, but part of the beauty of mathematics lies in the creative elements that are needed to be effective problem solvers; skills that are dependent on students' higher level thinking. When teachers foster and promote WCD, they also develop more creative and higher level thinking skills in students (Mercer, 2008; Roberts & Billings, 2009). Kuhn (2005) also links discourse to the development of thinking, and thus learning, and stresses that thinking is something that is typically done collaboratively. Kuhn's classroom discourse model, the theoretical model used for this study, depicts the collaborative nature of discourse (see Figure 1). In this model, students are identified by a number; e.g. S1, S2, and S3. The arrows and corresponding numbers indicate to whom the question was directed and the order in which these interactions were made.

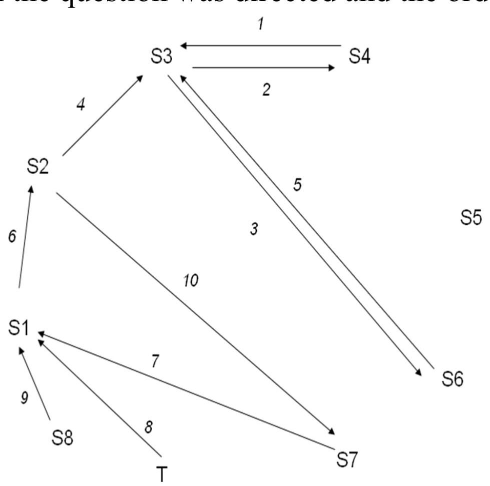

Figure 1: Kuhn's Authentic Classroom Discourse model

Providing timely and appropriate feedback on student learning is important in supporting student learning. During WCD, when students verbally construct their responses, teachers can more accurately assess students' understandings or misunderstandings (Clarke & Sullivan, 1990). Furthermore, mathematical WCD provides assessment opportunities that may not be evident in other forms of assessment (Falle, 2004). Misconceptions, be they general or specific, can be addressed in a timelier manner and addressed immediately. As an assessment strategy, few other strategies can provide more real-time information than WCD.

Methodology

Since teachers' perceptions were the focus of this study, a phenomenon that is naturally dynamic and flexible, I used a four phase qualitative case study with a grounded theoretical approach (Guba & Lincoln, 2005). A grounded theoretical approach was used because I placed significant emphasis on the interpretations and meaning that teachers had towards discourse as evident in their interviews and observations. Also, as a result of the teachers' observed interactions in an authentic and naturalistic setting, during which thick descriptions were created, theory was inductively generated (Bogdan & Biklen, 2007).

Phase 1 of this study surveyed 30 middle level public school mathematics teachers to determine their beliefs about WCD. These teachers came from four different schools that had similar demographics in academic mathematical achievement, ethnic and cultural diversity, and size of the student populations. Nine teachers from Phase 1 who indicated that they believed WCD was a highly effective strategy for teaching mathematics to adolescents were chosen for Phase 2. Phase 2 consisted of semi-structured interviews to better understand their perspectives and the strategies the teachers used to facilitate WCD. For Phase 3, three teachers were selected from the Phase 2 group for classroom observations. These teachers were selected based on the complexity, richness, and diversity of their responses during the semi-structured interviews. In essence, these three teachers seemed to exemplify WCD as a method of supporting mathematics learning for all students. Phase 4 consisted of follow-up interviews with the same teachers from Phase 3 so that I could better understand their perspective as it related to their actual practices.

Findings

Phase 1

For Phase 1, I administered a four item survey which identified the degree to which teachers valued WCD. The first three items of this survey were: 1) It is important for students to talk about mathematics as an entire class; 2) When the whole-class has a discussion about mathematics, it can be more beneficial than in small groups; and 3) I feel that I can comfortably facilitate discussions with the entire class. Using a one-to-five scale, with one meaning they strongly disagreed, a five meaning they strongly agreed, and a three was listed as being neutral teachers indicated their perceptions. The fourth item read, "I plan for whole-class discussions" and gave four options. The four options were: A) nearly daily, B) about one to two times a week, C) about once every two weeks, and D) once a month or less. The results from the first three items indicated that nearly every teacher agreed or strongly agreed with the items. Finally, for the fourth item, 20 of the 30 teachers indicated that they planned for WCD either one to two times a week or nearly daily.

Phase 2

For the second phase, semi-structured interviews helped clarify the perceptions teachers' had towards WCD. All of the teachers believed that WCD was a useful instructional strategy in some manner even though many of the teachers misunderstood. Many thought discourse was related to something negative; "discourse is something off track or off tangent," or "discourse to me would mean something is not going very well or varying opinions on a topic, I guess. Discourse to me sounds bad." However, when asked to describe whole-class discussions, one teacher who initially misunderstood the term discourse described it as "talking, taking turns talking. Maybe I would start them on a topic and it's an organized talking that has one spokes person. It is just not craziness going on." This is similar to the types of responses by the teachers who conveyed an understanding of WCD. One such teacher described WCD as “ways of getting all of the students actively engaged in contributing to verbal expressions of a specific topic.”

The interviewed teachers also believed that there were specific benefits for teachers and students alike. For the students, these benefits included a perceived increase in understanding and greater individual accountability in learning. The benefits for the teachers were the ability to check for understanding in a timely manner and the ability to adjust instruction and intended learning opportunities based on students’ understanding.

In addition, the teachers believed they had specific responsibilities in order to reap these benefits; the most frequently reported responsibility was being a “facilitator.” One teacher said, “I feel like a facilitator. I literally sit back and just let them debate themselves. And that is what I think is what we should be doing; letting the kids talk but you can kind of steer them too.” Other teachers indicated that they needed to create supportive and organized classrooms so students would feel comfortable participating; “to eliminate that fear of giving the wrong answer by showing them that you can give the right answer.” Teachers also believed that being a facilitator meant that they needed to probe student thinking by asking different types of questions and gradually shift more of the questioning responsibilities to the students; students should be the ones asking questions to each other without the teacher needing to prompt others to do so.

The teachers were also quite aware of the specific social, physical, and cognitive needs of adolescents and tried to create learning environments that were sensitive to these needs. Several teachers stated that adolescents often do not want to be put in situations that could compromise their social or emotional security. For these “shy” students, the teachers believed it was best to not press the student for a response but rather leave them be. One teacher even indicated that for, “the ones who are really shy it is not healthy to try and get them to say anything. I get this sense that they are not comfortable, they are not able to speak; they are not sure about themselves.”

Finally, many of the teachers described meaningful WCD in terms of increased participation and/or clear and observable physical cues such as more students raising their hands, a sense of excitement to share responses, and expressions on faces. Only three of the nine teachers described meaningful WCD in terms of an increase in students understanding. Carrie, one of the teachers observed during Phase 3 believed meaningful WCD was evident when “they no longer look at me to determine the validity of a student’s response; they just keep going, they ask each other instead.” Another teacher thought that meaningful WCD in their classroom was apparent in students’ higher quality response.

When asked about the techniques or strategies they used to promote meaningful WCD, their responses related to four common types. These included the use of questions (seven responses), small groups (nine responses), various technologies (four responses), and impromptu instructional modifications (six responses). These eventually became part of the teacher-generated framework (TGF) used in Phase 3.

Phase 3

In the third phase of the study, three teachers were selected for observations; they were Carrie, Erin, and Samantha. After analysis of the Phase 2 data, an initial theoretical framework of how teachers perceived WCD was created. This TGF was composed of two separate facets: 1) Required roles and duties of the teacher and instructional strategies frequently used by teachers to facilitate WCD and 2) the desired student traits that would be evident as a result of implementing WCD. The first element for Facet 1 is grounded in the teachers’ beliefs that their primary duty was to facilitate WCD and this meant to keep the discourse flowing and on topic by asking the class different types of questions. Facet 1 also included their strategies for promoting WCD; using small groups, technologies, and/or impromptu lesson modifications. The second element of Facet 1 was based on the teachers desire to increase engagement and participation to include many students. For Facet 2, teachers perceived that there would be specific and observable traits demonstrated by the students. They believed that through their efforts in facilitating WCD (Facet 1) there would be at least two traits that would aid in promoting the learning of mathematics. First, participation would increase because all students would be actively engaged. Next, students would provide higher quality responses; an indication that they understood the mathematics being learned.

Based on the TGF, not all teachers' perceptions of WCD corresponded with their actual practice. Although, two of the teachers, Erin and Carrie, used several of the strategies identified in the TGF and thus had perceptions that closely mirrored their practice in most instances. Carrie's perception of WCD seemed to be identical to her practice though there were few student-to-student discursive interactions because all student responses were first funneled through her. Erin's perceptions were also relatively close to her practice but she relied heavily upon voluntary responses. Even though she believed WCD was important for all students, it was typically the same few students who provided responses and many students were never selected or asked to participate. Carrie did not include every student in the WCD each class period either, but she used name cards to randomly select students to participate. Furthermore, Erin also had limited student-to-student discursive interactions because she also used the same wagon wheel (Okolo, Ferretti, & MacArthur, 2007) or funneling effect used by Carrie (See Figure 2).

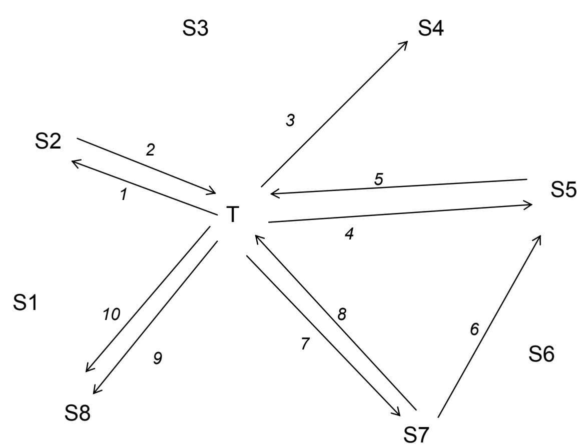

Figure 2: The wagon wheel structure most commonly used.

This technique more closely aligns with a traditional initiate, response, and evaluation (IRE) form of communication. Finally, Samantha's perception of WCD did not appear to reflect her practice at all. Even though students were in groups, these groups were not used to promote meaningful WCD. Furthermore, her use of voluntary responses and IRE structures limited the responses to the same few students in nearly every discursive interaction.

Phase 4

In this final phase of the study I wanted to learn more about two emergent themes framed around the following questions: 1) How did the observed teachers come to their understanding of

WCD and 2) can WCD support adolescent students' affective development? These two questions arose from the interviews and observations with each of the respective teachers.

Each teacher reported arriving at their understanding of WCD through different ways. Erin came to her understanding of WCD through her experiences in the classroom but also mentioned that her understandings had changed based on the initial semi-structured interview. As a result of this interview she decided to think about how she could implement WCD more often as she did not previously view WCD as an effective strategy for teaching and learning mathematics. Carrie stated that she came to her understanding of WCD through observations of other teachers along with frequent reflections on her own practice. Observations were important to her because she was able to witness various strategies and then incorporated or modified them as needed. Whereas Samantha believed strongly that learning was a social endeavor and this was based on her previous college course work. During this interview Samantha also revealed that she believed that WCD was a naturally occurring phenomenon in her classroom and thus she did not need to plan for, and in fact, never planned for WCD during the observations.

Each of the three teachers talked about how WCD supported adolescents during this time of their life as they grow and develop socially and emotionally. The teachers said that WCD helped students gain and foster a critical sense of belonging within the classroom. The teachers were aware that adolescents constantly seek acceptance from their peers and thus WCD provided an avenue through which students gained recognition as being part of the classroom and validation of their ideas. Carrie believed that by selecting students that did not typically participate and asking them to contribute they would feel more connected to the class; this was counter to many of the thoughts and beliefs of the other teachers interviewed.

Implications and Recommendations

After careful analysis of the findings from each of the four phases of this study, there were four areas of concern that were identified that could have an impact on students' learning of mathematics with respect to WCD. These four areas were: 1) Connecting pedagogy to the nature and needs of adolescents, 2) creating cultures of participation that are inclusive to all students, 3) assessing for learning through collaborative and formative methods, and 4) shifting responsibilities from the teacher to the students to promote relational understanding.

With respect to connecting pedagogy to the nature and needs of adolescents, teachers also clearly expressed a need to be mindful of students' affective development. Unfortunately, this led to numerous students not being included in the mathematical learning experiences. In essence, students were frequently, and unintentionally, being marginalized. However, discourse between peers is an essential element in students' learning and development thus all students should be involved (Grennon, Brooks and Brooks, 1999).

Next, with respect to creating cultures of participation that are inclusive to all students, it is important to remember the tenets echoed by the NCTM (2000); meaningful interactions are built upon cultures of collaboration. Classroom cultures of participation are collaborative, value all individuals' comments and ideas, and maintain accountability for all members within the learning community for contributing to and shaping the understandings that arise through shared discursive interactions. This also means that strict adherence, deliberately or otherwise, to the use of voluntary responses combined with IRE structures of discourse need to be reevaluated. Reliance on voluntary structures cannot effectively support classroom cultures of participation. Employing random selection techniques like the ones Carrie used could be one way to begin to shifting from IRE structures to more inclusive practices.

When it comes to teachers using WCD as an assessment tool, Stiggins (2002) reminds educators that the primary purpose of assessments is to assess for learning rather than an assessment of student learning. What this means is that teachers need to be using assessment strategies that intentionally and deliberately aim to improve student learning. An implication of such deliberate assessment strategies is that teachers need to be continually probing students' thinking to learn what misunderstandings may exist. While each of the three teachers observed indicated that WCD was a beneficial method of assessing for learning, rarely were student responses challenged. In addition, when teacher-centered IRE approaches are combined with voluntary responses, as they were in these cases, only a select few students' learning will ever be assessed at any given time. Therefore, the class discourse could not be accurately relied upon as a formative method of assessment to gauge all students' learning.

Questioning plays an important role in the assessment process of WCD. Stein et al. (2008) suggest focusing on developing deliberate and meaningful questions prior to the implementation of the lesson based on anticipated difficulties students may have. In doing so, teachers will be better prepared to facilitate WCD. Furthermore, teachers will not need to think of questions to ask in the moment and can then focus on the quality of the responses provided and thus help students link the student-directed WCD to the intended learning outcomes.

The final area of concern dealt with shifting the primary responsibility of facilitating WCD from the teacher to the students. WCD should be a student-centered phenomenon, which means that the students need to be the leaders within the classroom; each of the three observed teachers stated as much during their interviews. But, because of an over use of IRE structures, teachers maintained the intellectual authority during the WCD. As a result, there was no apparent shift in responsibility to the students.

Despite these concerns, promising change was found in the classrooms that strove to create cultures of participation. In the observed classrooms that created cultures of participation, or had elements that supported a culture of participation, students were invited, encouraged, and expected to participate and contribute to the mathematical understandings that were generated.

Conclusion

This study was based on Larson and Bartlo's (2009) recommendation that classrooms should shift from structures that are teacher-centered, wherein the teacher is the primary source of knowledge, to student-centered that require all students to be active participants in the learning of mathematics. Mathematics should be a collaborative social endeavor that is inclusive of all adolescent learners; it should be explored, digested, and realized within a learning environment that places students at the forefront (Okolo et al., 2007; Roberts & Billings, 2009).

Within this context, this study examined middle level public school mathematics teachers' perceptions of WCD and revealed surprising discrepancies between teachers' beliefs and their actual practices. This study also identified a Teacher Generated Framework in Phase 3 that supported the facilitation of WCD so that more students could be actively engaged in generating mathematical understandings.

While this study was limited, cases of this sort assist in constructing theory and methods that support future research into the perceptions and instructional techniques used to facilitate inclusive whole-class discourse. Further research into the interaction and relationship between teachers' perceptions of WCD and the instructional tools and strategies they use to implement and facilitate meaningful WCD will help create a more precise understanding of this phenomenon.

PUPILS' ARTICULATION OF MATHEMATICAL THINKING

Ahmad Fadzillah Bin Hanafiah
Ministry of Education
ahmadfadzillah@gmail.com

Brunei Primary mathematics curriculum (2006) advocates teachers on the use of questions to promote mathematical thinking in the pupils. When the pupils are asked and probed of their thinking, meaningful learning will take place. Research has made it clear that probing questions is one of the effective ways to promote thinking among the pupils. This paper describes the study which reports on the pupil's responses to teachers' questions supported by the pupils' responses in the interviews. It was observed that the pupils' responses in the lessons observed were mainly choral and consist one to three word answers. The pupils' answers were mainly repeated reasons and repeated procedures. This finding is consistent with the pupils' responses in the interview where the responses were mainly learned procedures and reasons that did not show explicit mathematical thinking.

Introduction

With reference to the Brunei new upper primary mathematics syllabus published in 2006, one of the aims is to develop "the ability to solve mathematical problems and think clearly and logically" (p. 3). In line with this aim, a few specific objectives of the new mathematics curriculum stated in the document are to "develop the ability to estimate, develop spatial awareness, develop basic skills in collecting and interpreting data, develop the ability to communicate mathematical ideas clearly, tackle non-routine problems systematically and apply what has been learned to solve real problems" (*Mathematics Syllabus for Upper Primary Schools 2006*; p. 3). These developments, in particular the development of mathematical thinking and problem solving, are stipulated to be developed through the interaction between mathematical content and mathematical processes. Mathematical thinking is identified as one of the mathematical processes. In the document, mathematical thinking has been described in several sub-processes such as "Guessing and checking, Drawing diagrams, Making lists, Looking for patterns, Working backwards, Classifying, Identifying attributes, Sequencing, Generalising, Verifying, Visualising, Substituting, Re-arranging, Putting observation into words, Making predictions, Simplifying the problem and solving part of the problem" (p. 5). These sub-processes clearly represent explicit views of mathematical thinking in terms of behaviour and articulated thinking.

In terms of behaviour, Wertheimer (1961), a gestalt psychologist, described the components of thinking from a phenomenological point of view. He mentioned that thinking processes can be noticed in terms of the behaviour. Such terms can be in the form of comparing and discriminating (identification of similarities and differences); analysing (looking at parts); induction (generalisation); experience (collecting facts or grasping structure); experimentation (looking for differences between possible hypotheses); associating (items together and recognising relationships); guessing and checking, trial and error and learning on the basis of success (with or without appreciating structural significance). This view suggests that mathematical thinking assists pupils to realise the necessary knowledge or skills for solving a particular problem. It should also be seen as the driving force behind such knowledge and skills. This is referred to as the "mathematical attitude" (Katagiri, 2006). This view of mathematical thinking seems to be comparable with the current conceptual framework of the Brunei mathematics curriculum which shows interwoven attitudes, processes and content (Khalid, 2007).

In terms of articulated thinking, Mason, Burton and Stacey (1982) identified four fundamental mental processes that show the progress of mathematical thinking: specialising – trying special cases, looking at examples; generalising – looking for patterns and relationships; conjecturing – predicting relationships and results and convincing – finding and communicating reasons why something is true. This view is related to the ability of the primary pupils that can be developed. When mathematical thinking is viewed in terms of articulated thinking, patterns of thinking develop (Fennema & Carpenter, 1996). The ability of the pupils to think by themselves, accompanied with conceptual understanding, strategic competence, adaptive reasoning, and productive disposition are the new goals in education (Kilpatrick, Swafford & Findell, 2001). The Brunei mathematics curriculum implemented in 2006 has similar goals and as previously mentioned, emphasises understanding through the development of mathematical thinking.

A study by Cheeseman & Clarke, (2001) investigating articulation of mathematical thinking, found that young children (aged 5 to 7 years old) could give an account of mathematical events from their perspective. They also found that through interviewing them, the children could recall at least part of their conversations with the teacher during the mathematics lesson. They concluded that when teachers used interaction that challenged children to think about their mathematical understanding, they could reconstruct thinking. In the study, they reported that 59% of the children could talk about their learning as a result of the lesson — some at a factual level, some at a procedural level and some at a conceptual level. The ability demonstrated by these children suggested that mathematical thinking can be fostered even at an early age.

Research Problem and Research Question

The objective of the study is to investigate the mathematical thinking of the pupils by observing the types of pupils' responses and supports the findings with the information from the interviews to assess whether year 5 pupils showed any development of their articulated mathematical thinking. Hence, the study seeks to answer the question: What are the pupils' responses to teachers' questions that show mathematical thinking in learning mathematics?

Research Methodology

Sample

The participants in the study were year 5 pupils who ages between 10 to 11 years. A total of 40 pupils were randomly selected from five year 5 classes situated in Tutong and Brunei Muara districts. These pupils were seen asked by the teachers in the respective classes during the observation.

Instruments

The research utilised two codes- the first code was used to analyse the pupils' responses in the observation sessions and the second code was used to analyse the responses of the pupils in the interviews. Table 1 and Table 2 show the two codes mentioned.

Table 1
Pupil Response Codes

Pupils' Responses	Description
No response	No answer to teacher's question.

Chorus	Whole class responds orally to teacher's question.
Individual pupil	Denotes which pupil answers (enables link with probing question).
Correct	Correct response given.
Partially correct	Partially correct response or incomplete response.
Incorrect	Incorrect response given.
Explanation	Requires pupil to give information.
Justification	Requires pupil to explain answer or strategy.
Question	Pupil answers the teacher's question with another question.

Table 2
Categories of Responses for Aspects of the Interviews

Aspects of Interview	Categories of Responses
Recall of events	• no recall • could talk about the learning with video • recall spontaneously
Description of events	• no description • describe the action • describe the outcome • describe the event from their perspective • describe their reasoning / justify their thinking
Explanation of their learning	• no explanation • learned nothing • learned a behaviour not mathematics • remembered factual information • learned how to do something
Explanation of their thinking	• no explanation • simple explanation of thinking such as "compare the digits" • explicit description of thinking • explain/reconstruct thinking, reasoning, justifying, evaluate thinking

The interview data provided qualitative accounts of the pupils' mathematical thinking in terms of the following areas:

- recall of a task or an activity;
- description of events;
- explanation of their learning;
- explanation of their thinking.

The areas above followed the "complementary accounts methodology" used by Clarke (2001) to capture pupils' accounts of their mathematical thinking.

Data Analysis

The pupils' responses in the observations were coded, counted and converted into average to highlight which type of responses was the most. Similarly, the pupils' responses in the interviews data were also analysed by counting frequency of mention or recurring regularities which then were categorised. After the responses from the observation and the interview were collected, the responses were entered into the SPSS package for quantitative analysis.

Result and Discussions

a) Analysis of the Observation of the Pupils' Responses

Table 3 illustrates the total frequency of each category of pupils' responses in the ten lessons observed. The table is divided into two. The first three rows illustrate the frequency counts of "No response", "Chorus" and the "Individual pupil" categories. The other rows show the breakdown of the individual responses which were coded as "Correct", "Partially correct", "Incorrect", "Explanation", "Justification" and "Question". Some of these responses were classified under two categories which explain the discrepancy between the total frequency counts and the individual frequency counts. Only the chorus and the individual responses were added to give the total frequency of pupils' responses. The "No response" frequency counts were not included because the study focused only the pupils who responded to the teachers' questions to demonstrate mathematical thinking.

Table 3

Total Frequency of Pupils' Responses in Primary 5 (10 lessons)

Pupils' Responses	T1	T2	T3	T4	T5	Average
No response	0	2	0	1	1	
Chorus*	27 (64.3%)	41 (65.1%)	38 (76%)	42 (85.7%)	56 (70%)	72.2%
(Individual pupil)*	15 (35.7%)	22 (34.9%)	12 (24%)	7 (14.3%)	24 (30%)	27.8%
Total*	n = 42	n = 63	n = 50	n = 49	n = 80	
Correct (I)	13 (31%)	21 (33.3%)	12 (24%)	5 (10.2%)	22 (27.5%)	25.2%
Partially correct (I)	2 (4.8%)	0	0	0	0	1.0%
Incorrect (I)	1 (2.4%)	1 (1.6%)	0	2 (4.1%)	2 (2.5%)	2.1%
Explanation (I)	6 (14.3%)	3 (4.8%)	0	0	1 (1.3%)	4.1%
Justification (I)	0	0	0	0	0	0
Question (I)	0	0	0	0	0	0

The frequency counts of the pupils' responses revealed that the prevalent response in each lesson observed was the whole-class choral response. On average, 72.2% of the responses made to each teacher were choral. Consider the following discussion between the pupils and teacher T2 on identifying the numerator and the denominator of 3/4:

T: "Which is greater, three or four?"
P: "Four." (Chorus 1)
T: "Which is less numerator or denominator?"
P: "Numerator." (Chorus 2)
T: "Yes, the numerator is less than the denominator."
P: "Yes." (Chorus 3)
T: "So the numerator is smaller than the denominator. It is called proper fraction."
T: "Why do we call proper fraction [sic]*?"*
P1: "Numerator is small." (Explanation 1)
T: "Yes the numerator is smaller than the denominator."
(An episode of verbal exchanges in one of T2's lessons.)

The episode revealed that the chorus responses 1, 2 and 3 were one word answers because the questions posed by the teacher were closed questions. When the teacher asked for the reason why it was called a proper fraction, which was an open question, the explanation given by P1 was a repeated reason provided by the teacher earlier in the exchanges. The responses given by individual pupils were the other category of pupils' responses with an average of 27.8% per teacher. Individual responses were important in two ways. First the coding assisted the writer to trace for probing questions and second, to analyse whether the responses were reflecting thinking or not. Consider the following verbal exchange between a pupil named Abdul Mateen and his teacher, T1, on conversion of 3 centimetres into millimetres.

T: "Can you convert 3 cm into mm?"
P: "Yes."
T: "So, what is the answer?"
P: "30 mm."
T: "Why not 40 mm?"
Abdul Mateen: "Because it is 3 cm."
T: "Why is that?"
Abdul Mateen: "Because 1 cm is 10 mm."
T: "So what do you think?"
Abdul Mateen: "So 3 cm is 30 cm."
T: "Good."

(An episode of a verbal exchange between Abdul Mateen and T1.)

In the verbal exchange between Abdul Mateen and his teacher, T1, the responses given by the pupil demonstrated development of thinking as his teacher asked him subsequent sets of questions. However, the responses were one to three word answers only and were not explanatory or justifying in nature. Further information on the nature of the pupils' thinking is discussed in the interview section.

Eighty individual responses were coded with an average of 25.2% correct responses per teacher, indicating that the individual pupils had answered what the teachers intended. On the other hand, per teacher, an average of 2.1% of the pupils' responses was incorrect. Among the individual responses were explanatory type answers with an average of 4.1% per teacher. As mentioned earlier, the explanatory answers were repeated reasons which proved to be parroting and regurgitating the teachers' reasons or explanation.

b) Analysis of the Interviews with the Pupils

The interviews were conducted with individual pupils to collect data on their mathematical thinking developed through the teachers' questions posed in the lessons observed. The interviews were necessary to support the pupils' responses coded in the lessons observed. The interviews were conversational in style. The writer conducted the interviews in a bilingual manner which was a mixture of Brunei National Language (Malay) and English because most of the pupils had difficulty expressing themselves in English. Another reason was that English was the second language spoken by these pupils. The data generated from the pupils' interviews were quantitatively and qualitatively analysed. All of the interviews were recorded, transcribed in full and coded following the study done by Clarke (2001) on pupils' accounts of mathematical thinking.

Recall of Events

In Table 4, about 85% of the year 5 pupils interviewed were able to recall the learning that occurred in their respective lessons without the need to use the video recording as a prompt for the recollection of the learning. Only one pupil (5%) did not respond to the "unstructured" question "Do you remember when the teacher asked you questions during class?" and the other 10% could give responses when the video recording was played for a short period of time.

Table 4
Categories of Responses of Recall of Events

Category of response	**Year 5**
No recall	2 (5%)
Could talk about their learning with video	4 (10%)
Recall spontaneously	34 (85%)
Total	n = 40

Description of Events

In Table 5, the pupils' recall of events were categorised in two categories. The first was that some of the pupils described the events in terms of what they had done in the lesson. This made up 70% of the pupils' responses. The other description described the outcome (30%).

Table 5
Categories of Description of Events

Category of Response	**Year 5**
No description of interaction	2 (15%)
Describe the action	28 (70%)
Describe the outcome	12 (30%)
Describe the event from their perspective	0
Describe their reasoning/justify their thinking	0
Total	n = 40

Three examples of the interview scripts from each level showing description of actions are presented as follows:

Interviewer: "So what did you say or do here?"
Abdul Mateen: "I use ruler and a measuring tape to measure lengths."
Siti Nur: "I multiply using vertical format."
Mohd Adi: "I counted 2/2 as 1 and 2/2 as 1 to make 2 and 1/2."

Three examples of the interview transcripts from each level describing the outcome are shown as follows:

Interviewer: "So what did you say here?"
Abdul Azli: "We compare fractions. Which one is bigger or smaller."
Amirah : "Change times from minutes to seconds."
Lailan: "Comparing fractions less than and more than."

There was no evidence of the pupils in either group describing the events from their perspective nor describing their reasoning or justifying their thinking.

Explanation of Their Learning

Table 6 shows 80% of the pupils in year 5 were able to specify their learning and they stated that they had learned something in the lessons. However, 5% of the learning was behavioural learning such as drawing, shading and colouring which was not mathematics. In addition, one of the twenty pupils in year 5 was unable to specify mathematical learning.

Table 6

Categories of Explanation of Their Learning

Category of Response	**Year 5**
Unable to specify learning	2 (5%)
Learned nothing	0
Learned a behaviour not mathematics	2 (5%)
Remembered factual information	32 (80%)
Learned how to do something	32 (80%)
Total	n = 40

An example of the description of doing something is cited below:

Interviewer: *"What did you learn today in mathematics?"*
Siti Juliana: *"Fractions."*
Interviewer: *"What about fractions?"*
Siti Juliana: *"Divide an apple into half and quarters."*
Interviewer: *"Can you give me an example of fraction from that?"*
Siti Juliana: *"One out of two parts because there are four equal parts"*

Explanation of Their Thinking

With reference to Table 7, the number of pupils who were able to explain their thinking for year 5 was significantly low at 5%.

Table 7
Categories of Explanation of Their Thinking

Category of Response	**Year 5**
No explanation of thinking	38 (95%)
Simple description of thinking	2 (5%)
Explicit description of thinking	0
Explain/reconstruct thinking, reasoning, justifying, evaluate thinking	0
Total	n = 40

Only four of the total number of pupils in year 5 who were interviewed was able to give a description of their thinking. Their thinking was a simple description instead of a more explicit manner. However, it is difficult to ascertain whether these pupils have been trained to think because the time constraints of the study did not allow the writer to follow the pupils in greater lengths. Therefore, the category of simple description of thinking was appropriate to code instances of thinking among the pupils interviewed. Unlike some pupils in Clarke's (2001) study, none of the forty interviewees offered an explicit description of thinking or reconstructed, justified or evaluated their thinking.

Conclusion

In conclusion, the pupils' ability to articulate their thinking can be attributed to some extent, to the quality of teachers' questions. Hence in this light, it is recommended that the pupils should be asked more open ended questions particularly probing questions to provoke thinking. While it is a fact that English is not their first language, the language use to formulate the questions should be common in all subjects for familiarity and for easy understanding. This is important so that the pupils can not only articulate but also use the language for discussion and argumentations. Discussion and argumentations can be cultivated from problems which are familiar, open and non routine. The Brunei primary mathematics syllabus has provided problems that are routine and non routine embedded in every topic. Hence, it is crucial for teachers to use these as a platform for lessons to inculcate discussion and argumentation. Further study can be done to consider mathematical thinking in terms of behaviour and attitude. Such studies may also include bigger sample size and covers the four districts in Brunei.

MECHANISMS FOR SCIENTIFIC DEBATE IN REAL ANALYSIS CLASSROOMS

Paul Dawkins
Northern Illinois University
dawkins@math.niu.edu

Kyeong Hah Roh
Arizona State University
khroh@math.asu.edu

This study uses a constructivist model of scientific debate to analyze two accounts of fruitful debate from separate real analysis classrooms. Our findings highlight the importance of such debate for helping students reconcile differences between their mathematical conceptions and others held in the community of practice through various forms of "conceptual triangulation" on shared mathematical tasks.

Cobb (1994) argued that mathematics instructors must coordinate the dual processes of promoting individual student's construction of mathematical understanding and enculturating students into standard mathematical meanings and processes. However, in many university classrooms, student conceptions remain tacit to the extent that incompatibilities between individual notions and standardized meanings go unrecognized or unresolved. This study investigates scientific debate as a pedagogical means by which members of the community of practice gain more faithful access to one another's mathematical conceptions such that both the construction of meaning and enculturation to standard mathematics can proceed in tandem. Moreover, we highlight mechanisms by which scientific debate can arise and proceed in the undergraduate classroom.

This study presents two accounts of successful scientific debate from different undergraduate, real analysis classrooms. In each, we identify the means by which the debate began and proceeded toward resolution. The studies came from the independent research of the two authors, and this paper represents one product of our collaboration to combine observations from separate instances of non-traditional, real analysis instruction.

Theoretical Framework

We draw the language of our framework for analyzing scientific debate from radical constructivism as outlined by Von Glasersfeld (1995). Von Glasersfeld posits that concepts are developed by individuals as tools for making sense of their ongoing experiences. As people cannot have access directly to one another's thoughts or concepts, all communication stands as new experiences for a participating individual. The need for scientific debate arises when the conceptions held by one or more parties engaged in a discussion are incompatible for the purposes of the task in which they are collectively engaged. The end goal of scientific debate is for the parties involved to adjust their respective conceptions as related to the given task until they achieve mutual "fit" or compatibility. Thus the basic constituents of scientific debate are (1) two or more communicating parties who each have constructed (and evoked) (2) one or more conceptions as related to (3) a given task (or set of tasks) being discussed.

The resolution of scientific debate depends upon the ability of the individuals involved to first recognize incompatibility between their respective conceptions and negotiate the process of altering their conceptions until compatibility is achieved. Once the incompatibility is recognized, the parties involved must reflect upon their conceptions to adjust toward mutual fit. Freudenthal (1991) described several modes of reflection under the umbrella of "shifting one's standpoint" (p. 105). The two most pertinent for the present analysis are shifting the vantage from which a task is being viewed or transferring the concept under consideration into an alternate task. Either form of shifting extends the discussion in new directions and allows constituent parties to identify the incompatibility(ies) in their thinking and adjust toward achieving mutual fit. We call these methods of shifting viewpoints "conceptual triangulation."

Study 1

The first study was conducted during a real analysis course at a large American public university. This course consisted of two class meetings per week (80 minutes in length) for 15 weeks. The first author of the paper observed the classroom as a researcher, and interviewed the instructor and 5 students most weeks of the semester (usually 7-9 interviews total) regarding the course content and classroom discussions. The flow of classroom discussion and all communication on the board were logged in the form of written notes.

The classroom differed from traditional Definition-Theorem-Proof instruction (Weber, 2004) in that the instructor expected the students to make determinations regarding the mathematical body of theory, and at least some students adopted this role in their own deliberations (Dawkins, 2009). The instructor always guided the classroom discussion, but consistently involved members of the class by presenting them with choices (of alternate definitions or possible theorems) about which the class voted and generated examples, arguments, and counter-arguments. In order to involve students in defining, the instructor only introduced definitions after the class discussed sets of examples and/or less formal ideas to which definitions correspond (e.g. continuity and connectedness).

The episode in this study occurred during the class session leading up to the definition of the limit of a function at a point. The instructor's intended to present examples that did and did not have limits due to restricted domains so as to motivate the standard requirement that limits only be defined at cluster (accumulation) points of the domain of the function. We divide the episode according to the instructor's introduction of various examples to guide the class to an agreement regarding those cases in which the limit can and cannot be defined. We particularly trace the viewpoints expressed by two of the most vocal students in the discussion, Cyan and Locke.

Results from Study 1

The instructor began class by writing the expression $\lim_{x\to p} f(x)$ on the board and asking, "When does this have meaning?" She introduced the function $f(n) = .5n$ defined only on the natural numbers and assigned the task of finding the function value and function limit at $x = 3$. Cyan asked about the domain restriction, and the instructor replied that this was a choice they must make. When she requested the value of the function at 3, both Cyan and Locke offered the value 3/2. Cyan explained that the image of $f(x)$ approaches 3/2 as x approaches 3.

In line with the instructor's original intention of highlighting what "approaches" means, she introduced a second task involving a function f defined as x^2 on the interval $[-1,1]$ and $f(5) = 2$, but not defined elsewhere. She asked, "What does it mean for x to approach 3?" directing their attention to the sequence $x = 1 - 1/n$. One student suggested that x must be "arbitrarily close" to 3. The instructor affirmed that "x approaches 3" means "x must get arbitrarily close to 3." No one expressed disagreement regarding the existence of this function's limit. The instructor then asked the class about the image of the first function at the point 2.75. Locke suggested that they should "pretend that it is in the domain." Initially the instructor did not directly respond to this assertion and pursued the topic of cluster points. She pointed out that there are no points in the domain arbitrarily close to 3 other than 3, but Locke expressed further confusion on this point and Cyan argued that x-values near to 3 should be considered. The instructor asked the class whether they want to "pretend" and asked Locke and Cyan directly whether they agreed that $f(5/2) = 5/4$. She articulated her surprise at their willingness to “define analysis” according to pretending. Locke protested that, “Just ‘cause it’s not in the domain doesn’t mean that the function doesn’t apply to it.” Though Locke and Cyan agreed in concert to evaluate the function at 5/2, other students articulated disagreement because of the original assumptions of the task.

To extend the discussion, the instructor introduced another task with a function defined as $(x^2-9)/(x-3)$ when $x \neq 3$ and as 0 when $x = 3$. She pointed out that $f(3) = 0$ and by constructing a table of values argued that the function limit at 3 equaled 6. The instructor persisted in questioning the class whether their answers depended upon “pretend games.” When students in the class expressed agreement that the function value was 0 while the limit was 6, she asked why the limit in the prior example had to equal 3/2. Cyan protested that, “We know the behavior of [the previous] function.” Locke, seeking to clarify the source of the disagreement, explained, “We were thinking of [the first example] on R to R.”

The instructor then introduced a final task with a function defined as $.5n$ on the natural numbers, but which had a vertical asymptote at $x = 3$. She pointed out that she could “pretend” that the original function was extended this way. Cyan continued to disagree with her because, “We have more information.” Locke revised his claim that the original function was defined everywhere. The instructor asked the class, “Do you see how un-mathematical this is?” Later, when she summarized their discussion of cluster points, the instructor wrote on the board: “In order to make sense of $\lim_{x\to p} f(x)$, there must be points in the domain of f arbitrarily close to p. Otherwise $\lim_{x\to p} f(x)$ becomes a ‘pretend game’.” In later interviews, both Locke and Cyan expressed understanding and agreement with the instructor’s argument that functions defined only on the natural numbers cannot have limits.

Discussion of Study 1

Cyan’s assertion and connected explanation regarding the first function limit made the instructor aware that their conceptions of the task were not fully compatible. She initially assumed there was a difference between their conceptions of limits, though it turned out that Cyan and Locke’s conception of domain was incompatible with hers. Locke and Cyan’s conceptions of domain, which were formed at lower levels of instruction, may only exclude points at which functions are not well-defined (dividing by zero, roots of negatives, etc.) such that restricting a linear function to the natural numbers created confusion.

Once the first task revealed that there was some conceptual incompatibility, the instructor proceeded to introduce three related tasks intended to help Cyan and Locke to adjust their disparate conceptions toward standardized conceptions. The second task emphasized the “approaches” aspect of the function definition. The third task was intended to separate the function limit from the function value. When Cyan and Locke agreed with her assessment of the second and third task, the instructor understood that neither of these issues related to limits housed the disparity between Locke and Cyan’s thinking and her own.

After the instructor repeatedly addressed aspects of function limits, Locke called her attention directly to the issue of domain (though it had been mentioned repeatedly). He explained that he understood the original function to be defined for all real numbers. The final task the instructor introduced addressed the ambiguity of assuming the value of functions outside their stated domain. This example displayed the instructor’s conception of domain for Locke and Cyan, namely that it is equally mathematically valid to assume any possible function values for inputs outside of the stated domain. At the time of interview after this class meeting, both students reported agreement with the instructor’s assertion meaning that they had adjusted their conception of domain to “fit” the instructors’ (standardized) conception of domain relative to the tasks discussed in class. The differing assessments of the first task led the instructor, Locke, and Cyan to reflect upon their constituent conceptions related to the limits of functions. The instructor guided the students to triangulate their conception of the first task by viewing various constituent conceptions ("approaches", function values and limits, function domain) in alternate tasks. Ultimately they were able to resolve the scientific debate after three standpoint shifts.

Study 2

The second study was conducted as part of a teaching experiment (Steffe & Thompson, 2000) in a real analysis course at another large, American public university. The real analysis course consisted of two regular sessions (75 minutes in length) and a recitation (50 minutes in length, mainly for cooperative proof writing) for 15 weeks. The second author served as an instructor of the course. Eleven mathematics or secondary mathematics education students volunteered to participate in this study, working in three small groups. Although some content was provided in a traditional lecture style, instruction in the course mainly followed an inquiry approach, in which students were often asked to make and justify conjectures and to evaluate arguments. Each day, one student from each group was assigned rotationally as a group facilitator of the day. The facilitators were instructed to ensure that all members of their group share their ideas and thoughts freely with one another and help them attend fully to one another's perspectives.

On the day of the study, the students were asked to work with the following task: (1) Does there exist a real number x satisfying that for any $\varepsilon > 0$, $|x| < \varepsilon$?, and (2) If there does exist an x, is there any other real number x satisfying that for any $\varepsilon > 0$, $|x| < \varepsilon$? Prior to group discussion, the instructor gave the students a short time to think individually about the given task. The facilitator of each group then initiated group discussion by giving individual students time to present their initial thoughts about the task; group discussion followed in order to share ideas and form a consensus. After the group discussion, two students from each group were sent to the other two groups such that each group had a representative from all three original groups. Students in a newly formed group presented their original group's ideas and listened to students from the other groups. At that stage, students asked or responded to questions from other groups to understand the various ideas, without debating the validity of the ideas. After sharing ideas from different groups, everyone returned to their original group to compare and contrast their ideas with those of the other groups.

Student activities were videotaped, and students' written work was pen-casted (synchronized with their voice). We focused on individual students' shifting standpoints regarding various approaches to the task and how those approaches were expressed by different people. We then examined how this type of practice allowed constituent parties to identify and reconcile the incompatibilities in their thinking.

Results from Study 2

Our analysis in this paper focused on a group of four students: Alan, Andy, Mary, and Oliver. When the students received the task, Andy was assigned to be the facilitator of the group. After a short time to think individually, Andy asked his group to share their thoughts on the task. Oliver first suggested choosing $x = 0$ and then $x = \varepsilon - 1/\varepsilon$. Mary expressed that she did not figure out what she was supposed to do for the task, but liked Oliver's idea. Alan also said that he did not understand what the task was about. Oliver reinterpreted for Alan that the task was questions about the existence and uniqueness of x, to which Alan assented. Finally, Andy agreed with Oliver to consider 0 as a value for x, and claimed that 0 would be the unique value for x. At this point, the students did not address the fact that Andy and Oliver's answers to the task were incompatible. After everyone presented his or her initial thoughts, Oliver went on to explain:

Oliver: Choose x to be x = ε – 1/ε since ε > 0 instead of going to be equal to 0. And so, ε – 1/ε means that no matter how small you get [uses two fingers for a small increment], there's something slightly smaller. That [x] will be less than ε and the absolute value of that [x] would be less than ε.

Alan and Mary immediately accepted Oliver's idea of choosing x in terms of ε, and suggested 1/ε as another value for x. At that point, no one in this group noted that their values for x might not satisfy the inequality $|x| < \varepsilon$ unless $\varepsilon > 1$, however, Andy realized that his answer was distinct. He insisted that 0 was the only value for x because the inequality should be satisfied for any positive value of ε, but the other group members did not accept Andy's claim. Alan contended that there were plenty of other ways to choose x such as 1/ε.

Andy: As just ε gets smaller and smaller, that puts more and more of a restriction on what x can be. And ε will never actually reach 0, but it will get very, very close to 0, and could basically be any number other than 0. [...] So, the only value of x that would actually work is 0, as far as I can tell.

Alan: Actually, I think this is not true. In other words, that x is not unique. [...] What I'm thinking is along the line of what Oliver talked about. 1/ε is always gonna be smaller than ε because ε is greater than 0. [...] Since we're trying to show the existence of x, choose x = 1/ε. Alright? So, then, you can choose, I mean, there are certainly plenty of other choices, [...] if you choose x = 1/ε, ε can be anything. ε is arbitrary as long as it's, uh, it's arbitrary, 'cause [ε is] an arbitrary real number greater than 0.

Andy: Um, well, x has to be a fixed value though. You can't put it in terms of ε.

Oliver: I believe, I believe you can because ε is arbitrary.

Mary: [...] It's already part of the inequality. So, I don't understand why you don't think we can set x as 1/ε.

At that point, the students were all aware of the arbitrariness of ε in the task. However, Andy's understanding of how the arbitrariness would work in the task was quite different from the other students; Andy treated the arbitrariness of ε to imply the decrease of ε towards 0. This created a restriction on choosing x independently from ε, whereas other students allowed the dependence of x on ε. Alan, Mary, and Oliver seemed to perceive the given statement as, "for any $\varepsilon > 0$, there exists a real number x such that $|x| < \varepsilon$," in which the order of the variables x and ε was reversed. (It is a similar result to Dubinsky and Yiparaki (2000) and Roh's (2010) studies, in which students tended to perceive ∃∀ statements as ∀∃ statements.) Nonetheless, the students did not yet recognize that the difference between the ways they were interpreting the given statement were incompatible. Alan was first to adopt a standard interpretation of the statement, and Oliver adjusted his viewpoint because x preceded ε in the given task. By the end of the group discussion before exchanging groups, Alan, Andy, and Oliver agreed that due to the order between x and ε in the given task, x must be defined prior to ε.

Alan: x comes first, right?

Alan: Yeah, so we can set x to be ... Oh, wait! ε doesn't exist when x comes into existence. So, we can't set x to be 1/ε.

Andy: Yeah, 'cause you need to pick a value of x but if you haven't defined what ε equals –

Oliver: Yeah, I would guess that we're saying that due to the set up of the problem, 0 was the only choice that satisfies the first part. And, [reading part 2]. So, I would say due to the set up of the problem which is that x is identified first.

Andy: Yeah, I think that is probably the best way to go about it.

When the instructor asked the class to exchange groups, Mary still did not understand why 0 was the only value and 1/ε could not be chosen for *x*. Since she was reluctant to go alone to a different group, Oliver decided to stay with her when exchanging group members. It was Elise who joined from a different group and helped Mary understand why 0 should be the only value for *x*. Elise reported that her group concluded that 0 is the unique value for *x* in the task, and presented how her group came to this conclusion. First, Elise balled her right hand into a fist to represent *x* and stated, "'there exist' is an existence where you choose it [*x*]. There it's just one number. You have to choose *x* and that [*x*] can't change." She moved her left hand horizontally, back and forth over her fist, to represent 'for any $\varepsilon > 0$, $|x| < \varepsilon$.' Tapping the fist, which was not moving, Elise also stated that, "It says 'for any ε,' that means no matter what you choose for ε, this number [*x*] has to work." She then demonstrated contradictions in cases where nonzero real numbers were chosen for *x*.

Elise: If I choose, […] like say I choose .5 [for x], I can choose an ε greater than 0 but less than x. […] So, the only thing that works for x is 0. […] But because 0 is the only number that works, there is not anything else. Because no matter what number you choose [x] bigger than 0, there will be an ε smaller [than x].

Elise's presentation led Mary and Oliver to reflect on their group's conceptions of the task. Oliver perceived that his conception and his group's prior explanations were compatible with Elise's explanation. He treated his conception that "*x* cannot be defined in terms of ε" as being compatible with Elise's conception that "*x* can't change" Mary perceived a distinction between her group's explanations and Elise's, and strongly preferred Elise's explanation.

Mary: We found the same thing for the first part. And the second part we thought of other ideas, but came to the same conclusion that there does not exist any other x's that satisfy the thing –

Oliver: For the exact same reasons. So if you change the order of how ε is in front, so 'for any ε > 0, does there exist an x that's element of the reals?', then we would be able to choose something but otherwise we aren't able to define something [in terms of ε].

Mary: and how you explained it is exactly how I needed to hear it 'cause they weren't saying it, anything like how you're saying it.

Elise: Yeah, that one. Because you have to go in order, it's like you do there exist –

Mary: They said the order part, and then I still didn't get it until you [said] –

When the instructor asked students to return to their original groups, Andy recapitulated what he learned from Elise's group as well.

Andy: The group [Elise's] that I went to basically had the same train of thought that we did. […] they came up with the fact that 0 would work, and they also came up with that it was the unique solution to the problem. They were also thinking about being able to put it [x] in terms of ε but realizing that you can't do that because x comes first. […]

Mary: The girl [Elise][…] explained it exactly how you just explained it. I didn't understand that concept before […]but now it makes sense. Like, I heard you guys saying it. I just couldn't understand why, and now I get it.

The group discussion after students returned to their original groups affirmed the sense of mutual compatibility between all of the group members' assessment of the given task, where *x* must be defined before ε. The group exchange provided students with an opportunity to compare various perspectives by attending to alternate interpretations made by different people. Consequently, students in this group, Mary in particular, were able to shift their standpoints toward the one shared by their group members.

Discussion of Study 2

The need for scientific debate in Study 2 arose when Andy's answer to the task was not the same as that of Alan, Mary, and Oliver. The students constructed different conceptions about the arbitrariness of ε and the relationship between ε and x in the given task. The classroom environment introduced iterative stages into the scientific debate. Time for individual thinking followed by articulation enabled the students to share various answers to the task in the group and recognize the incompatibility between Andy and the other students' conceptions. Alan's explanation that, "ε doesn't exist when x comes into existence," helped Alan and Oliver adjust their conception regarding the logical dependencies between ε and x in the task. The group exchange allowed Mary to view the task in terms of Elise's gesticulatory explanation and adjust her conception to fit that expressed by her group mates previously. The final exchange with the original group affirmed the sense of mutual fit.

Conclusions

Analyzing the structures of the two studies reveals parallel mechanisms that initiated the scientific debates and allowed them to proceed. In both studies, a *shared task* presented the means by which different parties in the classroom could assess the relative compatibilities of their conceptions of key mathematical topics (e.g. domain, limits, interdependence of quantities in a logical proposition). The phrase "shared task" should be distinguished from other mathematical activities in the classroom in the sense that questions which are presented and promptly solved by the instructor (for instance) do not provide the opportunity for different parties to bring their conceptions to the attention of other members of the class. By a shared task, we mean a mathematical task that is introduced into the class discussion with the expectation that multiple parties can or will share their understanding thereof with other members of the class. In both studies, the shared task revealed conceptual incompatibilities, but the scientific debate was advanced by means of conceptual triangulation. In Study 1, the introduction of alternate shared tasks with the same constituent conceptions provided the means of triangulation. In Study 2, the stages of class discussion introduced other students' conceptions expressed in terms of alternate explanations as a means of triangulation on the same task. These two processes of triangulation are represented in Figure 1.

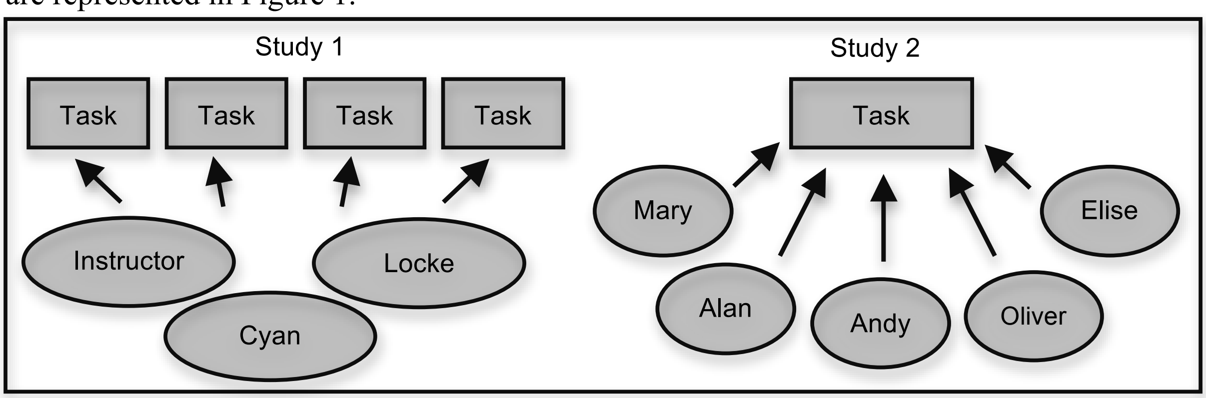

Figure 1. Alternate means of conceptual triangulation in the two examples of debate

Though the participant members of both debates achieved acceptable compatibility in their conceptions relative to the original shared task, the structures of the courses, which facilitated this progress, differed meaningfully. We classify both of the classroom environments in question as non-traditional proof-based instruction in large part because they involve shared tasks in which the students are expected to form and express their conceptions about the topics being discussed. However, in the first study the classroom discussion filtered through the instructor and she was able to leverage her knowledge of both analysis and of student difficulties in analysis to introduce tasks that would likely move the debate forward. In the second study, no alternate tasks were introduced, but students heard a variety of explanations of the same task. Thus the second debate progressed and reached conclusion without instructor intervention beyond setting up the parameters and responsibilities of group discussion. These studies highlight the importance of fostering scientific debate in the classroom; the confusion that each debate overcame could easily have remained latent in an alternate pedagogical setting. However, such exchanges take time. These studies describe two points in the middle of a continuum of real analysis pedagogy between presentation as in Definition-Theorem-Proof instruction and guided reinvention of standard mathematics (Gravemeijer & Doorman, 1999; Swinyard, 2008). Each yields benefits and drawbacks. The second study's structure empowered students to reach conceptual fit themselves; the former opened the door for a secondary discussion, prompted by the "pretend" term, on a meta-mathematical norm of operation that mathematicians must reason within the constraints of stated assumptions.

Our central claim about scientific debate mirrors that of Cobb, Boufi, McClain, and Whitenack (1997) when they said, "We… conjecture that children's participation in [reflective] discourse *constitutes conditions for the possibility of mathematical learning*" (p. 264). We do not claim that every student in the classrooms we described came to the same conclusions. We posit that classroom environments in which shared tasks arise and scientific debates are appropriately pursued enhance the probability that larger portions of the class will achieve higher degrees of conceptual fit. The process of adjustment toward conceptual fit between the members of the community of practice constitutes a means of tandem progress toward the dual classroom goals of student conceptual development and enculturation to standard mathematics.

EXPLORING THE DISCOURSE ON CONTINUITY IN RELATION TO LIMITS IN A BEGINNING-LEVEL CALCULUS CLASSROOM

Beste Güçler
University of Massachusetts Dartmouth
bgucler@umassd.edu

Students' informal views of the notion of continuity can present challenges as they attend to the precise aspects of various calculus concepts. This paper explores continuity in relation to the limit concept in a beginning-level calculus classroom. The study uses a discursive approach developed by Sfard (2008) to investigate the instructor's discourse on continuity and the realizations of limit it supports. This is followed by the comparison of the instructor's discourse on continuity with those of the students. The findings indicate that, despite the instructor's explicit focus on the relationship between continuity and limits by means of the precise definition of continuity, students mainly focused on the intuitive definition in the instructor's discourse. Therefore, students in this study realized continuity through dynamic motion but not through limits.

Introduction

In many undergraduate calculus courses and textbooks, a precise definition of *continuity* is often given after the discussions on the concept of limit (Hughes-Hallett et al., 2005; Weir, Hass, Giordano, & Finney, 2008). However, earlier assumptions about continuity may underlie learners' realizations of several calculus concepts. For example, the realization of infinity as a process that goes on indefinitely is based on the assumption of natural continuity (Lakoff & Núñez, 2000). Students' incorrect considerations of functions as rules given by a single formula also rely on an implicit assumption of continuity (Tall & Vinner, 1981). Similarly, research has identified many obstacles students have about limits resulting from a dynamic view of the concept, which is based on continuous motion (Tall, 1980; Tall & Schwarzenberger, 1978; Williams, 1991). In particular, Bezuidenhout (2001) argued that *limit implies continuity* and *limit as the function's value* are among the incorrect realizations of limit that are based on students' informal views of continuity. These studies suggest that students' basic informal realizations of continuity may later create obstacles as they attend to the precise aspects of various calculus concepts.

This study explores continuity in relation to the limit concept in the context of undergraduate mathematics education and addresses the following questions: (a) How is the notion of continuity introduced by the instructor in a beginning-level undergraduate calculus course?, (b) Which realizations of the limit concept does the instructor's discourse on continuity support?, and (c) How do the elements of the instructor's discourse on continuity compare and contrast with those of the students?

Theoretical Framework

The study uses a discursive lens, namely, Sfard's (2008) *commognitive* framework. The term *commognitive* combines the terms *cognition* and *communication* by considering thinking as an individualized form of communication. This lens considers discourse as the main unit of analysis, where discourse is defined as "the different types of communication set apart by their objects, the kinds of mediators used, and the rules followed by participants and thus defining different communities of communicating actors" (Sfard, 2008, p. 93). From this view, mathematics is a particular type of discourse that can be distinguished by its word use, visual mediators, routines, and narratives.

Word use refers to the ways in which words are used in a mathematical discourse. *Visual mediators* are the visible objects that are created to enhance mathematical communication. *Routines* refer to the set of metarules that characterize the repetitive patterns in the activity of participants of a mathematical discourse. *Narratives* refer to the set of utterances describing mathematical objects and their relationships that are subject to endorsement or rejection. The narratives of a mathematical discourse that are endorsed by the majority of the experts of the community are considered as true (e.g., definitions, theorems).

A critical feature of word use is *objectification*, which occurs through *reification* and *alienation*. Reification "is the act of replacing sentences about processes and actions with propositions about states and objects" (Sfard, 2008, p. 44), whereas alienation refers to "using discursive forms that present phenomena in an impersonal way, as if they were occurring of themselves, without the participation of human beings" (Sfard, 2008, p. 295). Said differently, objectification changes the talk about processes to the talk about end-states or mathematical entities. This study focuses on the participants' word use and routines in the context of continuity and its relationship to the concept of limit.

Methodology

This work is part of a case study that investigates the development of discourse on limits. The participants included one instructor and his section of undergraduate students taking a beginning-level calculus course in a large Midwestern university. For the instructor's discourse, the data consisted of field notes and eight video-taped classroom observations in which the instructor discussed limits and continuity. For the students' discourse, the data consisted of four students' responses to a task-based interview and the field notes taken during the interviews. The interviews were audio-taped and lasted between 53-76 minutes. Participation in the interviews was voluntary. The class observations and the interview sessions were transcribed with respect to the participants' utterances and actions.

Although the main focus of the interviews was the limit concept, in four of the six interview questions, students also had the opportunity to talk about continuity. There were two questions consisting of piecewise functions given in algebraic form. Students were asked to find the limit of the functions at the break points, and at positive and negative infinity. They were then asked to discuss the continuity of the functions. In another question, the students were given the graph of a function and determined the limits of the function at various points. They then discussed continuity of the function at those points. The final continuity-related question was an adaptation of Bezuidenhout's (2001) task, where students were given the statement $\lim_{x \to 2} f(x) = 3$. They were then asked if the following are true given the statement: (a) f is continuous at the point $x = 2$, (b) f is defined at $x = 2$, and (c) $f(2) = 3$. The purpose of this question was to investigate whether students had the difficulties *limit implies continuity* and *limit as the function's value*, which are based on assumptions about natural continuity.

Participants' word use was analyzed with respect to the degree of objectification in their discourse. Particular attention was given to the realizations of limit the instructor's and students' discourse on continuity supported. Consistent with Sfard's (2008) terminology, participants' word use was considered *operational* if they talked about limit as a process based on natural continuity; *objectified* if they talked about limit as a distinct mathematical object or a number that is obtained at the end of the limit process.

The operational word use on limits relies on words signifying continuous motion (e.g., [the function values] "approach", "get closer and closer to", "go to" [the limit L]). The objectified word use on limits, on the other hand, either relies on words signifying proximity (e.g., [the function values are] "arbitrarily close to", "within ε distance of" [the limit L]) or refers to limit as a particular number (e.g., "the limit is equal to five") or a mathematical object (e.g., "the limit exists", "we can find the limit by plugging in").

The following pseudonyms will be used for the participants: Dr. Brenner (the instructor); Amy, Jessica, Harry, and Keith (the students).

Results

The instructor's discourse on continuity

Dr. Brenner introduced continuity at the end of his discussions about limit and before the review session he conducted for the mid-term exam. He mentioned that he was going to give one intuitive and one mathematical definition for continuity and asked students to use the latter in the exam. Table 1 shows Dr. Brenner's intuitive definition of continuity. Since he did not utter any limit-related words in this definition, his word use on limits was not coded.

	What is said	What is done
[1]	So what is a continuous function?	He writes continuous functions on the board.
[2]	A continuous function is a function, and I am just going to say it in words, that I can graph without taking the chalk off the board.	He states these verbally.
[3]	So this is really all that we need to know, from an intuitive perspective, about continuous functions.	He states these verbally.
[4]	Continuous just means I can graph without taking the chalk off the board.	He states these verbally.

Table 1. Dr. Brenner's utterances about the intuitive definition of continuity

After introducing the intuitive definition of continuity, Dr. Brenner drew graphs of a variety of functions and discussed their continuity based on whether he could graph them "without taking the chalk off the board" (Table 1, [2], [4]). While doing so, he moved his hand along the graphs of the functions and mentioned that "approaching and graphing like this" could be thought as a "limiting process". Therefore, he relied on the limit process and whether he took the chalk off the board when determining the continuity of a given function from its graph. Dr. Brenner's discourse on the intuitive definition of continuity was based on dynamic motion where limit was considered as a process.

Dr. Brenner then introduced the precise definition of continuity and, unlike the intuitive definition, he wrote it on the board. Figure 1 and Table 2 show his precise definition of continuity.

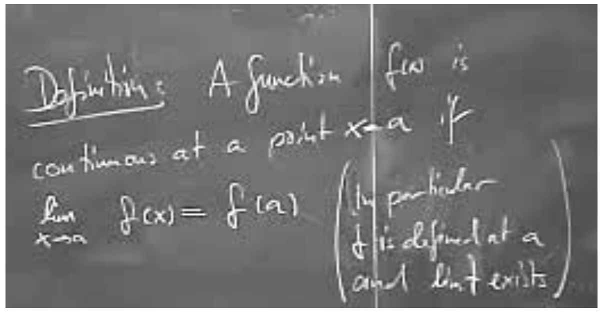

Figure 1. Dr. Brenner's precise definition of continuity

What is said	What is done	Type of limit-related utterance
[1] So let's try to make this precise.	He states these verbally.	
[2] A function f of x is continuous at a point x equals a if…	He writes these on the board but does not finish his sentence.	
[3] So what I want to say is what does it mean to be continuous at this point?	He states these verbally.	
[4] The limit has to exist and it has to equal to the function value.	He states these verbally.	Objectified
[5] So I need the limit to exist.		Objectified
[6] So the limit as x approaches a of f of x has to exist and equal to f of a.	He writes $\lim_{x \to a} f(x) = f(a)$ on the board.	Objectified
[7] Just writing this already implies that it [the limit] exists because it equals a number.	He states these verbally.	Objectified
[8] So, in particular, f is defined at a and the limit exists.	He writes these in parenthesis near the definition.	Objectified

Table 2. Dr. Brenner's utterances about the precise definition of continuity

Dr. Brenner's precise definition of continuity considered limit as a number (Table 2, [7]), which is equal to the function value at the limit point (Table 2, [4], [6]). His utterances about limits were objectified when he talked about the precise definition. In fact, 97% of his 90 utterances about limits in this lesson on continuity were coded as objectified.

It should be noted that Dr. Brenner did not explicitly talk about continuity prior to the lesson on continuity although his operational word use on limits in earlier lessons was based on continuous motion. The lesson on continuity was the first context in which he connected the notions of continuity and limit. Later in the lesson, he also said that "a question about continuity is a question about limits" and "the definition of a continuous function is given in terms of the limit" to emphasize the connections between the two concepts.

Dr. Brenner talked about *plugging in* as one of the possible ways of computing a limit in prior lessons. However, he put extra emphasis on plugging in as a means of computing the limit of a *continuous* function during the lesson on continuity. For example, while showing

$f(x)=\frac{x+1}{x^2+1}$ is continuous, he showed for every number a, $\lim_{x\to a} f(x)=\frac{a+1}{a^2+1}=f(a)$ and mentioned that he found that limit by plugging in. He then turned back to the precise definition of continuity and described the relationship between continuous functions and plugging in as illustrated in Table 3.

It is possible for students in Dr. Brenner's class to generalize this routine of plugging in for continuous functions to functions in general. However, Dr. Brenner explicitly highlighted that a function's value at the limit point is not related to the limit of the function at that point. He said: "To compute the limit as x approaches zero, what the function does at the point x equals zero is irrelevant. What only matters is what happens nearby". Similarly, he noted in an earlier lesson that

> The function value is something completely different. And here we see again that the actual value of the function at the point where we are looking at has very little to do with the limit. In fact, it has nothing to do with the limit.

What is said	What is done	Type of limit-related utterance
[1] In fact, we found this limit by plugging in.	He shows $\lim_{x\to a} f(x)=\frac{a+1}{a^2+1}=f(a)$	Objectified
[2] A continuous function is a function where we can always find limits by plugging in.	He states these verbally.	Objectified
[3] That is really what this definition says.	He goes back to the precise definition of limit he wrote on the board (See Figure 1).	
[4] f is continuous if you can find the limit at a by plugging in.	He first shows $\lim_{x\to a} f(x)$ and then $f(a)$ in the definition (See Figure 1).	Objectified
[5] That is exactly what the definition says.	He states these verbally.	
[6] In other words, function f is continuous at a if we can find the limit of f at x equals a by plugging in.	He writes these on the board.	Objectified
[7] These are great functions.	He states these verbally.	
[8] Continuous functions are exactly the ones that we can find the limit by plugging in.	He states these verbally.	Objectified

Table 3. Dr. Brenner's utterances about the relationship between finding the limit of a continuous function and plugging in

In summary, Dr. Brenner's intuitive definition of continuity supported the realization of limit as a process whereas his precise definition supported the realization of limit as an end-state: a number. In the context of the informal definition of continuity, his word use on limits was operational. In the context of the precise definition of continuity and following applications, his word use on limits was objectified.

The Students' Discourse on Continuity

When exploring continuity of functions at particular points, students did not talk about continuity through limits during the interviews. Amy talked about points of removable discontinuity as "jumps" and attended to the "open circles", or holes in graphs when exploring continuity of functions: "it [the function] is discontinuous because it has an open circle [shows the *y* value where the function does not attain its limit], which means that the function jumps essentially [moves her hand along the graph]".

Jessica's arguments about continuity were related to "connections" and "links". When discussing the discontinuity of one of the piecewise functions from the graph she drew, she said:

> It is discontinuous because we cannot find a connection or link between these two graphs [shows the piecewise graphs on the right and the left side of the *y* value where the function does not attain its limit]. You just need to focus on the point [shows the *y* value again] that connects both continuous functions.

In addition to her arguments about connectedness, Jessica also attended to the instances where the functions jumped: "It [shows the function value] jumped here [moves her hand along the graph]. It is not continuous".

Harry also used the word "jump" when talking about continuity of a function at a given point: "it is not continuous because the value [shows the *y* value of the function] jumps". He later mentioned taking his hand off the paper: "So the way I see if a function is continuous…Am I taking my hand off the paper? I had to take it off now [moves his hand along the graph] so it is discontinuous".

Keith's main routine when determining the continuity of a function was to find the instances where he took his pencil off the graphs of the functions: "It [the function] is continuous because you would not have to pick up your pencil. I know there is a more mathematical reason but I can't remember it now". Keith was aware that this explanation lacked mathematical precision but could not think of a way other than the intuitive approach of tracing graphs and reporting the points where he picked up his pencil as points of discontinuity. He also talked about jumps: "It [the function] is not continuous because there is a jump".

None of the students talked about continuity in relation to limits when examining the continuity of the functions in the interviews. This was also evident by the fact that none of the students uttered the word "limit" when investigating the continuity of a function. Instead, they often used the word "jump", which was not a word Dr. Brenner used when talking about continuity. Their approach was in accord with Dr. Brenner's intuitive definition of continuity in that they moved their hands along the graphs and attended to the instances where they took their hand or pencil off the graph. Note that, Dr. Brenner moved his hand along the graphs and determined functions' continuity based on whether he could graph them "without taking the chalk off the board" (Table 1, [2], [4]) in the context of the intuitive definition of continuity. He also noted that approaching and graphing in that manner could be thought as the "limiting process". So, by referring to limit as a process, his word use on limits was operational in the context of intuitive definition of continuity. Although the students also used dynamic motion, it was not clear how, or whether, they realized limits when exploring the continuity of functions since they did not talk about limits in that context.

When working on the adapted version of Bezuidenhout's (2001) task, which particularly investigated the student difficulties *limit implies continuity* and *limit as the function's value,* one student (Amy) talked about limits in relation to continuity.

Limit implies continuity refers to the idea that if a function has a limit at a point, then it must be continuous at that point (Bezuidenhout, 2001). Amy's arguments supported this idea during the interview. She said:

> Limits are only defined for continuous functions I believe. I am going to say it [the limit] does not exist because the point is open [shows the graph of the function where there is a hole] so it [shows the function] is not continuous.

When working on Bezuidenhout's (2001) task, Amy mentioned that if $\lim_{x \to 2} f(x) = 3$, then f must be continuous at the point $x = 2$ and said "so what I know about limits is that they can only exist if the function is continuous at that particular point [shows $x = 2$]". Therefore, Amy clearly thought that limit implies continuity. The other students did not show any sign of the difficulty throughout the interview. They drew graphs as counter examples in which the functions were discontinuous but had limits. However, none of them explicitly referred to continuity when reasoning about their graphs. Instead, they just showed their graphs and said the limit existed.

Limit as the function's value refers to the idea that when finding the limit of a function at a given point, it is sufficient to look at the function's value at that point (Bezuidenhout, 2001). This view of limit is in close relation to the routine of plugging in the limit point to the function to find the limit of the function at that point. Amy also showed signs of this difficulty. She argued that the statement $\lim_{x \to 2} f(x) = 3$ implied the function is defined at $x = 2$, and $f(2) = 3$. Her main routine when finding the limit of a function at a given point was to plug in the limit point to the function. If she obtained a number, she reported it as the limit value; if the function was not defined at the limit point or if the function did not attain its limit value, she mentioned that the limit did not exist. Jessica, Harry, and Keith consistently attended to the right hand and the left hand limits and whether they were equal to each other when finding limits. Even though they utilized plugging in when applicable, they did not generalize this routine to all functions and showed no sign of considering limits as function values during the interviews. They all drew graphs as counter examples in which the limit of the function at the limit point was not equal to the function value. Yet, they did not explicitly refer to continuity when reasoning about their graphs but used phrases of the form "limit exists but the function value is different".

Note that considering *limit as the function's value* through plugging in is consistent with the assumption of continuity in that, in order for the routine of plugging in to work, the function must be continuous at the limit point. Therefore, it is not surprising that Amy agreed with both of the ideas *limit implies continuity*, and *limit as the function's value*. According to her, if limits existed only for continuous functions, then the limit value had to be equal to the function's value.

Dr. Brenner explicitly mentioned that a function's value at the limit point was irrelevant to the limit of the function at that point. However, he also frequently mentioned one could find the limit of continuous functions by plugging in. Although he used different function types (e.g., piecewise, trigonometric, rational, etc.) for which the routine of plugging in could not be used when determining limits, the routine supported Amy's focus on the function values when computing limits. On the other hand, his work with a variety of functions rather than everywhere continuous polynomials may be why the other students did not show signs of the difficulties. Nevertheless, those three students' realizations of continuity were still limited to the intuitive rather than the precise definition.

In summary, students in this study did not talk about limits when exploring continuity. Students' discussions on continuity were based on the graphs they drew and the informal definition of continuity rather than limits even when their exploration of continuity immediately followed their computations of limits for the functions. Amy's discussions of continuity when exploring limits resulted from her incorrect views about limits. The other students could provide accurate counter examples for the statements investigating the relationship between continuity and limits but could not elaborate on their reasoning through the precise definition that connects these two notions. Despite the instructor's extensive focus on continuity in relation to limits, students' discourse on continuity was based on dynamic motion but not on limits. Therefore, although their routines supported the realization of limit as a process, their lack of utterances about limits did not enable the categorization of their word use on limits as operational or objectified.

Discussion

While a lesson devoted to continuity may highlight the mathematical definition and how continuity is related to the limit concept, students' previous informal experiences with continuity may interfere with their development of mathematically rigorous realizations of the concept. Although the lesson on continuity was the first time students in this study were formally introduced to the notion in this classroom, it was clear that they had some previous realizations of continuity. First, they often mentioned the word "jump" when talking about discontinuity, which was not a word the instructor uttered in the lesson. Second, Dr. Brenner did not write his intuitive definition on the board and so did not leave a written trace (e.g., in the form of class notes) for students to refer to. Yet, the intuitive approach dominated the students' discourse on continuity. Further, the word "continuous" is a commonly used everyday term. Therefore, students' use of the word "jump" may be related to their early learning experiences (e.g., with teachers and textbooks using the word "jump" as well as with daily uses of the term continuity).

Some elements of the instructor's discourse seemed to help the students identify the mathematical features of continuity that were different than their previous realizations. For example, Dr. Brenner used a variety of function types that challenged the common assumptions about continuity. Moreover, he explicitly highlighted that a question about continuity was a question about limits, and the function's value was irrelevant to the limit value. On the other hand, some other elements in his discourse (e.g., plugging in and his "taking the chalk off the board" routine) may have perpetuated the dynamic view in the students' discourse on continuity.

The dominance of the dynamic view in students' discourse on continuity has some implications for their discourse on limits. Besides the difficulties mentioned here (*limit implies continuity,* and *limit as the function's value*), research has identified other difficulties about limits that are based on tacit assumptions regarding natural continuity through dynamic motion. Therefore, students' common assumptions about dynamic motion need to be challenged. It might be important for instructors to use the lesson on continuity during which they relate continuity to limits as an opportunity to highlight the *qualitative* differences between an intuitive, motion-based approach and a precise, static approach to the notion.

The mathematics education community values using student thinking to develop mathematical concepts, but the nuances of this practice are not clearly understood. For example, not all student thinking provides the basis of productive discussions. In this paper we describe a conceptualization of instances in a classroom lesson that provide the teacher with opportunities to extend or change the nature of students' mathematical understanding—what we refer to as Mathematically Important Pedagogical Opportunities (MIPOs). We analyze classroom dialogue to illustrate how this lens can be used to make more tangible the often abstract but fundamental goal of pursuing students' mathematical thinking.

Research in mathematics teacher education suggests the benefits of instruction that builds on student thinking (e.g., Fennema et al., 1996), but such instruction is complex and difficult both to learn and to enact (Ball & Cohen, 1999; Feiman-Nemser, 2001; Sherin, 2002). Often opportunities to use student thinking to further mathematical understanding either go unnoticed or are not acted upon by teachers, particularly novices (Peterson & Leatham, 2009; Stockero, Van Zoest, & Taylor, 2010). Despite a growing number of teachers who are convinced of the value of student thinking and the need to encourage it, neither teachers nor those who educate them have a clear understanding of how that thinking can best be used to develop mathematical concepts (Peterson & Leatham, 2009; Van Zoest, Stockero, & Kratky, 2010). We address this issue by providing a conceptual framework for thinking about the mathematically important pedagogical opportunities provided by student thinking.

Although skilled teachers and teacher educators often intuitively "know" when important mathematical moments occur during a lesson and can readily produce ideas about how to capitalize on them, the literature reveals a construct that is not well-defined. Ideas related to these instances are mentioned in many different ways. For example, Jaworski (1994) refers to such opportunities as "critical moments in the classroom when students created a moment of choice or opportunity" (p. 527). Davies and Walker (2005) use the term "significant mathematical instances" (p. 275) and Davis (1997) calls them "potentially powerful learning opportunities" (p. 360). Schoenfeld (2008) refers to such moments as "the fodder for a content-related conversation" (p. 57), as "an issue that the teacher judges to be a candidate for classroom discussion" (p. 65) and as the "grist for later discussion or reflection" (p. 70). Schifter (1996) spoke of "novel student idea[s] that prompt teachers to reflect on and rethink their instruction" (p. 130).

It is clear from this literature that these instances, whatever they are called, are important to mathematics teaching and learning. It is also clear that there are some critical mathematical and pedagogical characteristics of such moments. In particular, references to them allude to important mathematics, pedagogical opportunities, and student thinking. We consider these three criteria and focus on their intersection as being the location of Mathematically Important Pedagogical Opportunities (MIPOs). A better understanding of the MIPO construct can inform the work of facilitating and researching teachers' use of students' thinking in mathematically productive ways. One difficulty in learning to use students' mathematical thinking is that there are so many different ways it can interpreted and acted upon. As Lewis (2008) observed, "The 'real' classroom experience is elusive: each moment is experienced differently by the actors involved and their perceptions of those experiences change with time and reflection. The choices of what to focus on, which story to follow, are endless" (p. 5). One critical role that mathematics teacher education can play is to provide lenses, informed by research and advocated by the community at large, for teachers to use both as they teach and as they reflect on and learn from their teaching. The conceptual framework put forth in this paper is designed to be such a lens. In the following, we carefully define and describe the MIPO construct, and initiate a discussion about how teachers and teacher educators might profitably use it to support students' mathematical learning.

Defining Mathematically Important Pedagogical Opportunities

We define a Mathematically Important Pedagogical Opportunity (MIPO) as an instance in a classroom lesson that provides the teacher with an opportunity to extend or change the nature of students' mathematical understanding. To be considered a MIPO, an instance needs to meet two important criteria: it needs to involve *important mathematics* and be a *pedagogical opportunity*.

Mathematically Important

To be *mathematically important* in a given classroom, the instance must be centered on an idea related to mathematical goals for student learning. In the narrowest sense, this would be a mathematical goal for the lesson in which it occurs, but more broadly, it could also be related to the goals for a unit of instruction, an entire course, or for understanding mathematics as a whole (see Figure 1). In the first case, the instance may focus on a particular mathematical idea or connections among ideas within the lesson, while in the latter cases, the instance might involve making connections to other areas of mathematics or developing mathematical ways of thinking.

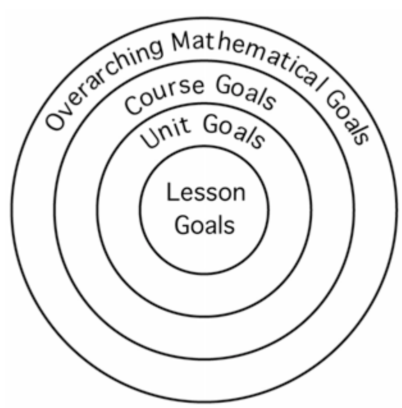

Figure 1. *Layers of mathematical goals to which a MIPO may relate.*

There appears to be an inverse relationship between the distance of the underlying mathematical idea in the instance from the goals of the day's lesson and the needed power of the mathematical idea for it to meet the mathematically important requirement of a MIPO. That is, the threshold for mathematical importance increases the further one moves away from the center in Figure 1. Furthermore, the mathematical importance of an instance is relative to the context in which it occurs. For example, an instance considered mathematically important in a calculus class because it highlights a subtlety in the topic being studied would not qualify as mathematically important in the context of an introductory algebra course if the students did not have the background knowledge to make sense of it. On the other hand, an instance that highlights something crucial about the nature of mathematics could qualify as mathematically important in any classroom in which it was accessible to the students and would help them to better understand mathematics as a whole.

When considering whether an instance is mathematically important, it is necessary to distinguish between its relationship to mathematical goals and to other goals for student learning. For example, helping students work more productively in small groups is a goal in many classrooms. Although this goal may support students' mathematical learning, the goal itself is not mathematical in nature, and thus, an instance related only to this goal would not be a MIPO—a MIPO must be firmly grounded in important mathematics.

Pedagogical Opportunity

In addition to involving important mathematics, a MIPO requires a *pedagogical opportunity*. Pedagogical opportunities are observable student actions that provide an opening for working towards an instructional goal. As such, pedagogical *opportunities* can be cultivated by the teacher, but cannot be created independently of the students. Teachers routinely make pedagogical *moves* that are designed to create opportunities for students to learn mathematics, such as posing quality tasks, asking probing questions, assessing students' progress and modifying their instruction in response to additional information. Well-executed pedagogical moves can, in fact, increase the likelihood of pedagogical opportunities in a teacher's class, but the opportunities themselves come from the students, not the teacher. For example, if a teacher were to introduce a theoretical student error into the class discussion to help clarify an issue that she felt her students were struggling with, it would remain a pedagogical move and not an opportunity until a student or students in the class interacted with the error publicly. A pedagogical opportunity must be grounded in an observable student action. Student actions, by providing insight into student engagement with an instructional goal, provide an opening for the teacher to work toward achieving that goal.

The Intersection of Mathematically Important and Pedagogical Opportunity

Mathematically Important Pedagogical Opportunities (MIPOs) occur at the intersection of *important mathematics* and *pedagogical opportunities*. In this intersection, observable student actions provide pedagogical openings for working towards mathematical goals for student learning. Although simple yes/no answers or other utterances may provide evidence *that* students are thinking, these openings only occur when student actions provide insight into *what* students are thinking about mathematical ideas. Thus, *observable student thinking* underlies the MIPO construct. Our conception of the relationship among important mathematics, pedagogical opportunities and student thinking is shown Figure 2. In this section we elaborate on each region in Figure 2 to further clarify the MIPO construct.

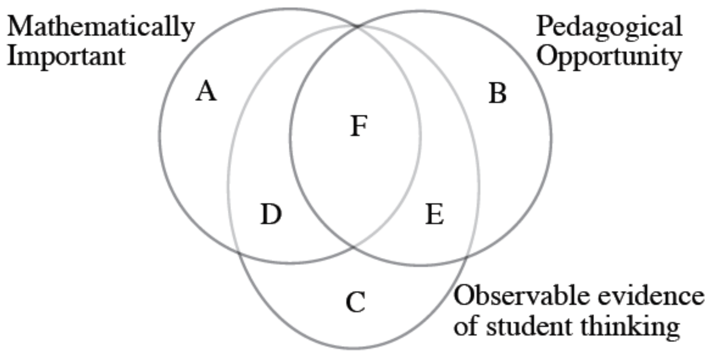

Figure 2. *Relationship among important mathematics, pedagogical opportunities and student thinking.*

Region A represents situations that are mathematically important, but neither provide evidence of student thinking nor a pedagogical opportunity. A teacher presenting important mathematical information would fall into this region, as would situations in which a teacher makes a pedagogical move to engage students with the mathematics, but students fail to provide observable evidence of having done so. In general, these are situations where important mathematics is present, but observable evidence of student thinking is not. For example, if a teacher were to make a mistake on the board related to important mathematics in the lesson, it would be a mathematically important moment. If the teacher corrects the error and moves on without student engagement with the error, this moment would not provide an opportunity to extend or change the nature of students' mathematical understanding. Student actions in response to the error that reveal their mathematical thinking, such as asking questions that illuminate the key mathematics behind the error, would provide an opening for working towards an instructional goal. This would put the moment in the intersection of the three areas in Figure 2, thus classifying it as a MIPO.

Region B represents situations where student actions do not provide evidence of student thinking and are not mathematically important, yet provide inroads for important pedagogical goals. For example, if a student were to get up to sharpen his pencil in the middle of a class discussion, the action would not provide insight into his thinking, but it could provide a pedagogical opportunity to talk about important classroom norms. In fact, pedagogical opportunities that neither provide evidence of student thinking nor relate to important mathematics seem to relate to general pedagogical rather than content-specific goals.

Region C represents student actions that provide evidence of their thinking, but the thinking is neither about important mathematics nor related to instructional goals. For example, a student might make a comment about the length of a homework assignment or reiterate a memorized fact. Although these comments give the teacher information about the student's thinking, they neither connect to important mathematics nor provide an opening for working towards an instructional goal, and thus, do not meet the criteria for a MIPO.

Region D represents situations that involve important mathematics and evidence of student thinking, but do not provide an opening for working towards an instructional goal. For example, a student in an algebra class could eloquently summarize why adding a constant to a linear equation corresponds to a vertical shift of the graph. While this comment could make a positive contribution by summarizing what students already know, it would not create the opportunity to extend or change the nature of students' mathematical understanding.

Region E represents pedagogical opportunities that provide insight into student thinking, but are not related to important mathematics. For example, a student might say, “I don’t see why I need to think by myself for one minute before I talk with my group.” This is not related to mathematics, but it does provide observable evidence of student thinking and would provide an opening for discussing the instructional goal of allowing individuals time to formulate their own thoughts before being influenced by others.

Region F represents situations in which student thinking about an important mathematical idea provides an opening for working towards a mathematical goal for student learning. This is what creates a MIPO. In this region, a student might, for instance, question or comment on a mathematical idea, verbalize their incomplete thoughts as they try to make sense of a mathematical idea, express incorrect mathematical thinking, make an error, or notice a mathematical contradiction. In all these instances, what is important is that the student thinking provides an opening for the teacher to make a pedagogical move that will extend or change the nature of students’ understanding of important mathematics.

Because student thinking is at the heart of every MIPO, there is no region in Figure 2 that includes both important mathematics and pedagogical opportunity without involving observable evidence of student thinking. It is when student thinking is made public that teachers have an opportunity to use that thinking to further students’ mathematical understanding. Although MIPOs can occur in any classroom environment, they are more likely to occur in classrooms that provide ample opportunity for students to make their thinking public.

An Example from the Literature

In this section we illustrate the MIPO construct by using it as a lens to analyze a piece of transcript taken from Leinhardt and Steele (2005, pp. 107-108). The episode comes from a 5th grade class discussion about finding output values for the rule 3x + 1 given different input values. The teacher, Magdalene Lampert, added ¼ as an input value to a table of input-output values and asked for the output. All of the previous input values had been whole numbers.

Soochow: One and three fourths.
T: How would you explain it please?
Soochow: *Because one-fourth times three is three-fourths and then you just add o– add a one*.
T: Okay, so first you times by three and then you add one.
T: Who can explain why one fourth times three is three fourths? Sun Wu?
Sun Wu: *One fourth, like one fourth of a pie and then somebody brings two more and one times three is three—three pieces of pie that came out of four pieces of pie?*
T: Okay, are they all the same size? Those three pieces of pie? Lisa?
Lisa: Yes
T: How do you know?
Lisa: Because if you’re adding one fourth times three you’re going to [—] [—] equal parts
T: Okay. Cause I’m, I’m taking three things that are all the same size. They’re all the size of one fourth. Ali?
Ali: *It could be one fourth [—] could be a whole one.*

T: Can you explain what you mean?
Ali: Can I come to the board?
T: Yes, here take this, [chalk] it's easier to see.
Ali: Here's like a big pie [draws circle and divides it into fourths]
T: Um-hum.
Ali: And then you could divide it into fourths, four pieces. *And then one fourth could be one (points to one segment of circle) and then would be like this one (points to the 1 on the input side of the chart).*
T: I don't understand what you mean. Does anybody else understand what Ali means? Bridgette?
Bridgette: Me-, he means that if you ha-, if you have one fourth and you make say you color in three of the four pieces [—] equal one whole.
T: Is that what you meant?
Bridgette: Yeah.
T: Okay, what do you think about that? Ali is saying three times one fourth is one fourth [*sic*]. Add one fourth and you'd get four so it would be just like here [points to the 4 beside the 1 in the function chart]. But the input number here was one [writes faint 1 in input column beside the 4] and now the input number here is one fourth [points to the ¼ in new chart]. What do you think Sun Wu?
Sun Wu: *He thinks the um, the one is like one fourth. But it's really one, another, four.*
T: What do you think about that Ali? [draws another circle]. How many fourths are there in one whole?
Ali: Four fourths [T draws new circle divided into fourths].
T: Four fourths? So if I was going to put a number in here I could put one and a fourth [*sic*] [writes in column]
T: Is there anything I could put in there besides one and a fourth? Elsie?
Elsie: Wouldn't it be one and three fourths?
T: Oh, I'm sorry. It should be one and three fourths like that anyway [changes chart]. Is that what you meant?
Elsie: Yeah.

We now use Figure 2 to analyze excerpts from this dialogue. In doing so we highlight examples from each region of the figure in order to help the reader distinguish instances that are MIPOs from those that are not. Lines 17 and 22 are examples of Region A, as in both cases the teacher emphasizes the same size of the pieces—an important mathematical principle. There is no student thinking involved and no pedagogical opportunity, but it is mathematically important. The student's inquiry in Line 26 about coming to the board provides an opportunity to address the teacher's expectations for sharing one's work and using tools in the class, but neither provides insight in the student's thinking nor involves important mathematics; thus, it falls in Region B. Lines 7, 24, 28, 36 and 51 provide evidence of student thinking, but do not involve important mathematics or provide pedagogical opportunities, thus they are examples of Region

C. Note that this dialogue also contains several student utterances that fell short of being observable evidence of student thinking (Lines 18, 40 & 59). Although these utterances suggest that the students are thinking, they don't provide insights into what they are thinking. In Line 56 a student provides a correction to an error made by the teacher. This is evidence of the student's thinking and also involves important mathematics, but does not provide a pedagogical opportunity, thus it falls in Region D. In Line 20, we see evidence of a student's thinking, but it isn't clear exactly what is going on mathematically. Because of this it isn't possible to determine if it involves an important mathematical issue or if it is merely a misspeaking. It does, however, provide a pedagogical opportunity to discuss the importance of the words that we use, thus it falls in Region E. Lines 9, 14, 30, and 47 all deal with observable student thinking, important mathematics, and pedagogical opportunities, thus fall in Region F. In Line 9, for example, Soochow's explanation of how to find the output value provided an opportunity to review how to multiply a fraction by a whole number. Sun Wu's explanation at Line 14 shifted the unit from the whole pie to a piece of the pie, providing a pedagogical opportunity for the teacher to engage her students in further discussion of this important mathematical idea. In each of these cases, the teacher expertly incorporated the MIPO into her instruction and it is possible to see how the discussion supported students in learning about important mathematics.

Discussion and Conclusion

Researchers and practitioners in mathematics teacher education advocate the use of student thinking as a means of improving mathematics instruction. Many teachers we have observed, particularly novices, seem to interpret this call to mean that *all* student thinking is equally valuable and, thus, should *all* be pursued in similar ways. We argue, however, that this is not the case. While teachers certainly need to carefully listen to all student ideas, this listening must be followed by thoughtful consideration of whether a particular idea or comment is worth pursuing.

By highlighting three critical components of instances in a classroom that provide opportunities to advance students' mathematical understanding—important mathematics, pedagogical opportunity and student thinking—the MIPO construct can be used as a tool to help teachers learn to distinguish moments that provide opportunities to further students' mathematical learning from those that do not. In addition, it provides a tool for helping teachers make sense of classroom situations—what Levin, Hammer and Coffey (2009) call *framing*. From this perspective, whether a teacher notices the value in an event depends on how he or she frames what is taking place during instruction. If, for example, a teacher views a student error as something that needs to be corrected, he or she is unlikely to consider the mathematical thinking behind the error or whether the error could be used to highlight a specific mathematical idea. On the other hand, a teacher who views an error as a site for learning is more likely to consider both the mathematics underlying the error and how it could be used to develop mathematical understanding. In considering whether an instance is a MIPO, teachers need to frame instances of student thinking in terms of both mathematical importance and the pedagogical opportunity they provide. Framing classroom events in this way has the potential to change the way teachers analyze and act upon instances in the classroom.

The conceptualization of MIPOs we have described provides both teachers and teacher educators a lens for analyzing the complexity of classroom mathematics discourse and a vocabulary for discussing the mathematical and pedagogical importance therein. We believe such a lens is significant because MIPOs are high-leverage instances of student thinking that have the potential to change the nature of mathematics instruction if incorporated well into a lesson. This conceptualization of MIPOs provides a tool that can help make more tangible the often abstract but fundamental goal of building on students' mathematical thinking.

THE ROLE OF LISTENING IN TEACHER TRANSFORMATION AND PEDAGOGIC PRACTICE

Stacy Reeder
University of Oklahoma
reeder@ou.edu

Summer Bateiha
Western Kentucky University
summer.bateiha@wku.edu

This case study research examines the transformation of one middle school mathematics teacher's pedagogic practices who has envisioned and enacted a problem centered learning approach to teaching and the factors he believes influenced and supported his transformation. The findings reveal that listening for this teacher infused the unfolding process of his transformation and is now an integral dynamic of his emergent mathematics curriculum.

Envisioning and enacting alternatives for teaching mathematics is a difficult and complex task often met with challenges from outside forces and influences and frequently hampered by our own inability to imagine that something else is possible. Our inability to see beyond our current and traditional ideas and ways of doing are often the greatest challenges we face in transformation. This study examined the pedagogic practices of one middle school mathematics teacher who has "seen" an alternative and who has enacted a problem centered learning approach to teaching mathematic (Wheatley, 1991) and further considered the factors he believed influenced and supported his transformation. He has envisioned and enacted and emergent mathematics problem solving curriculum in his classroom with and for his students. As his story of transformation unfolded the important role of listening for this teacher became apparent. Listening to his students became an inherent and integral part of the process of his transformation as he initially tried to transition from traditional pedagogic practices to a problem centered learning approach to teaching mathematics.

Theoretical Framework

Strengthening students' understanding of mathematics through communication is well established (Gose, 2009; Pugalee, 2001; Way, 2008) and is clearly emphasized in the National Council of Teachers of Mathematics (2000) *Principles and Standards for School Mathematics*. An important facet of communication for teaching mathematics is the discourse that occurs in the classroom between teachers and students but also between students and students when they articulate their own ideas and consider their peer's mathematical perspectives as a way to construct meaningful mathematics understandings. Developing a classroom environment and a curriculum wherein mathematical discourse is orchestrated and sustained requires of teachers to re-envision their role in the classroom as one of a participant in an ongoing conversation with mathematics at the center.

Carpenter and Fenema (1992) suggest that listening to their students may be a critical behavior for teachers wanting to develop more effective mathematics instruction. Davis (1997) further suggests that "attentiveness to how mathematics teachers listen may be a worthwhile route to pursue as we seek to understand and, consequently, to help teachers better understand their practice" (p. 356). Davis (1994) believes that listening is not just hearing what someone has said but rather an engaged physical activity.

> When two persons converse, for example, it can be *seen* that they are listening to each other as the actions of their bodies become bodily *interactions*. They lean toward and

> reach out for each other, momentarily unaware that they are violating the Western taboos on proximity, touch, and extended eye contact. They seem to focus in a way that suggests they are oblivious to the noise around them; they attend to each word and to each action as though nothing of importance had occurred prior to the discussion and nothing of importance awaits them at its end. They are unconcerned that their voices are perhaps too loud, their bodies too animated. (p. 268).

So listening is neither "motionless or silent" (p. 269). Listening, as Davis describes it, is an activity in which one is engaged and participating. Traditional approaches to the teaching of mathematics are often centered around the teacher's telling and presenting predetermined methods and procedures to an audience of quiet, motionless students who are assumed to be attending simply because they are quiet and motionless. Davis claims that this assumption cannot be made, that it is something other than the motionless silence of students that can make us aware that they are listening.

> In the classroom … as the novel is read or as the mathematical principle emerges, the teacher knows the students are listening not because they have ceased to move but because a certain rhythm or harmony is established – there is an awareness that each is immersed in and conducted by the same subject matter. The gazes are fixed not on the teacher nor on one another, but on that which is among them (1994, p.269)

Davis extends his consideration of listening as a lens from which teacher practice can be reinterpreted with his discussion of evaluative, interpretive, and hermeneutical listening. Evaluative listening "tends to forget its own responsibility in interactions (1997, p. 360). This type of listening occurs when the teacher is not listening *to* the students and the listening is focused on the elicitation of correct responses or "guiding" the students to a pre-determined method or solution path. Interpretive listening is described by Davis as listening *to* what learners are saying and perhaps even trying to understand what they are making sense of but still "listening *for* particular responses" (1997, p. 363). The kinds of questions that arise from this type of listening may allow for a greater range of responses than those accompanying evaluative listening but they may not foster much diversity. Hermeneutical listening is the third type of listening that Davis (1997) describes. It is the

> sort of listening [that] is an imaginative participation in the formation and transformation of experience. Hermeneutical listening demands the willingness to interrogate the taken for granted and the prejudices that frame our perceptions and actions. (p. 369-370)

Hermeneutical listening occurs when the teacher becomes "a participant in the exploration of … mathematics" (p.369). A teacher listening hermeneutically frees herself to participate with her students in the negotiated and evolving nature of interaction rather than simply listening to "take" the students to a certain predetermined point. The alternatives, evaluative and interpretive listening, engage the teacher in attempting to draw students into "*front-end* mathematics" where the "mathematics concepts [are] treated as though they … are independent of learners and their experience" (p. 339).

Methods

Data Collection and Analysis

This study was approached from the perspective of an in-depth case. This case was purposively selected (Schwandt, 1997) because it was thought to present insights into the impact of and interrelationships among changing ideas about mathematics and the enactment of a reform mathematics curriculum. Wesley, as he is called for this study, is a middle school teacher, who teaches seventh grade mathematics, pre-algebra and algebra I in a middle to upper income suburban public school in the Southwest region of the United States. Wesley is known throughout his state as an innovative teacher and has received some notoriety as a result of his innovative approaches and nontraditional teaching. While some may criticize and challenge his non-traditional approach to teaching mathematics, which includes problem centered learning and not using textbooks regularly, many praise his classroom approaches to teaching as being among the best and most effective in his district and state.

The purpose of this research was to identify and explicate a variety of aspects of this teacher's beliefs and classroom practices and gain insight into his story of transformation by addressing the following two focus questions:

1. What factors does this teacher consider to have influenced the transformation of his beliefs about mathematics teaching and learning?
2. What pedagogic practices does this teacher include in his implementation of a problem centered learning environment?

This study involved interviewing Wesley who had adopted and implemented an approach to mathematics curriculum grounded in problem centered learning (Wheatley, 1991; Wheatley & Reynolds, 1999) and constructivism (Ernest, 1996; von Glassersfeld, 1995) and observing and analyzing his classroom pedagogic practices for several months during a school year. The focus of these interviews was to explore the experiences Wesley believed were instrumental in developing his alternative view of the curriculum and in implementing a problem-centered learning approach in his classroom. Questions about his changing beliefs about mathematics and how those beliefs informed the curricular decisions he made were particularly probed.

The data collection for this study included audio-taped formal and informal interviews, field notes, transcripts of video-taped classroom interactions, and documents collected which were all transcribed as collected throughout the study. The transcripts were carefully read and coded for key words, and ideas, looking for themes or categories to emerge. Since one of the goals of the study was the telling of Wesley's teacher story, his interview transcripts were read and reread to determine if certain aspects of his experience needed to be further elaborated so other people reading about him might have a an understanding of him. In this way the data pertaining to Wesley's story were organized using an interpretational approach which is a "process of examining data closely in order to find constructs, themes, and patterns that can be used to describe and explain the phenomenon being studied" (Gall et al., 1996, p. 562). A reflective or interpretational approach to data analysis is described by Gall et al. (1996) as involving "a decision by the researcher to rely on intuition and personal judgment to analyze the data rather than on technical procedures involving an explicit category classification system" (p. 570). Thus, data were coded and as certain patterns or themes became apparent, new segments of data were continually and constantly compared within and across these themes and categories (Strauss & Corbin, 1998). This constant and continual comparison of data and emergence of themes guided the interviews with Wesley subsequent to the initial interview conducted.

Setting for the Study: Wesley's Classroom

To conduct research for Wesley's case two of his seventh grade classes, one pre-algebra class and an algebra I class were observed on a weekly basis for one semester. The first class each day was the algebra I class which was comprised of twenty-four students, thirteen of whom were boys and eleven were girls. The second period class was the pre-algebra class which was comprised of twenty-seven students, fifteen of whom were girls and twelve were boys. The students in both these classes would not be considered widely diverse in their abilities since for this district students are placed in these classes based on their standardized test scores and previous grades. Additionally, the racial background of the students in both these classes would not be considered diverse with only two or three students in each class being non-Caucasian.

The classroom was arranged with approximately thirty student desks divided into six rows that faced the front of the room where a white board was hung on the wall with two overhead projectors and screens. Along one side of the room there were seven computers placed on built-in desks with seven accompanying chairs. On the other side of the room was the teacher's desk with a computer and storage, all of which were built in and attached to the wall. Along the back wall of the room there were windows that extended the full length of the room under which were storage cabinets without doors that held a variety of manipulatives and materials for student access and use. On the surface of the cabinets there were containers with a variety of mathematics games, challenge puzzles, and transparency sheets with pens for student use. A Texas Instrument graphing calculator was attached with Velcro to each of the student desks for the students to use at their discretion. The walls of the room were decorated with a variety of posters, some motivational in nature and others presenting mathematical ideas, and with the many newspaper articles and awards that Wesley had won. The tops of the cabinets were lined with many trophies won in a city-wide stock market game.

Each of the class periods lasted fifty-five minutes and typically began with either a warm-up activity and discussion or some discussion regarding homework assignments from the previous night. Occasionally, the class period would begin with discussion about an assessment from the previous day. Regardless of the focus of the initial discussion in class, this time typically lasted about ten minutes until there was a shift of activity to the problem or task for that day. Following the opening discussion students were often given a choice of two or three tasks or problems that they could address during class. Students often voted on which problem they would consider first; this would also be the problem they would try to discuss prior to the end of class if they were ready. Many times the students would ask if they could continue to look at a problem they had first looked at maybe the day before or in some cases maybe a week or longer before. There would be some discussion about this and most often Wesley would agree that they could use their class time to continue looking at that problem if most everyone agreed. During problem solving students worked with their "partner" by quickly moving their chairs to face their partner or move across the room to an open seat near their partner. Also during the problem solving sessions students would frequently discuss their thinking with members of other groups and move around the room freely, to and from the white board "showing" another student what they were thinking or to retrieve manipulatives or a transparency sheet and pen. As students worked in small groups, Wesley moved around the room listening to students and infusing the conversation with questions, re-directing them or providing them with further challenge as needed. There were other times, however when the desks remained in rows and Wesley presented the problem solving tasks at the overhead. During these times, students would often be using their calculators or manipulatives to explore certain ideas or problems. Even when the desks remained in rows with Wesley primarily in the front of the room, students were free to work with one another and to discuss with those around them their thinking and ideas about the problem.

Typically, following problem solving where students had worked with their partners, but not always, class ended with student presentations of their solutions using the overhead and their transparency sheet. During this time the students presenting would discuss ways in which they thought about the problem that perhaps did not arrive them at a solution and then also ways in which they felt they had derived a solution for the problem. The students not presenting, those at their seats, would raise their hands and wait to be called on by those presenting to ask questions about the solution being presented or to share perhaps a different way they had in looking at the problem. Often this time would result in only two or three groups presenting their ideas with several students going to the board to explain other ideas they had regarding the problem. There were many days that the "end of class" discussion did not occur at the end of class but rather the next day or perhaps even a week later but they always came back to each problem for a time of discussion. All instructional activities emphasized student thinking, whether a warm-up activity, a problem solving task, or problem solving specifically with manipulatives, Wesley encouraged the students to complete the tasks in ways that made sense to them rather than providing them with specific procedures or algorithms for finding a solution (Wheatley, 1991; Wheatley & Reynolds, 1999).

Results

Wesley describes his pedagogical methods as beginning teacher as teacher-centered and a traditional type of approach during his first several years of teaching mathematics. "It was I'll explain or demonstrate from the overhead … the students would do problem sets and then they would come in the next day, we would grade that." It was not until a change in building administrators in the late 1980's that Wesley was encouraged to try something that varied from his traditional approach.

Trying New Things

In the mid-eighties the district where Wesley teaches experienced a change in superintendents. With a new superintendent whose focus was on "changing the direction of the district" and "innovation" several new building administrators were hired over a few years including a new principal at the middle school. This new principal, Wesley recalls, "was talking about cooperative learning and said to me 'when you get done with the book maybe you could go back and teach it without using the book, teach it with manipulatives, maybe some cooperative learning'." Describing himself as a "risk taker," Wesley believes that he was approached and encouraged by his administrator to try some new teaching approaches because he was team leader and because he was willing and open to consider new things. "So I started messing around with looking for some stuff I could do, some stuff we could do with cooperative problem solving and letting kids talk." Wesley continues, referring to urges by his principal to explore cooperative learning and the use of manipulatives with his students, "that kind of started this whole, my getting into this, my messing around with different things." It was these beginning experiences, trying some new and different things, letting his students talk and him listening to them, that created a sense of wanting or searching for more in Wesley.

Transformation Begins

During the summer of 1991, the school district's new superintendent, having been there only a couple of years, brought in Allan, a university professor whose primary research focus was children's mathematical thinking, for an elementary and middle school mathematics professional development workshop. Wesley recalls that something significant happened that day. "What happened that day that was different is that Allan started me thinking about mathematics, and what it is, what is mathematics, and so that's been an ongoing thing." While believing that the questions asked of him that day impacted him greatly, Wesley does not feel that it was this in isolation that began a process of change in the way he now teaches mathematics.

> I think I was impacted some by a middle school conference I attended with my principal. Some of the people there were talking about a learning pyramid that says something like you learn only 10% of what you read and then more if you have to teach it to somebody. I can remember wondering, "well, what about if you interact with others to help each other." So I know that I was really beginning to question some things and beginning to see the benefits of students working together to learn mathematics at that time. [Interview data]

Wesley also recalls that as he has reflectively considered how and perhaps why he has changed so significantly as a teacher that there were many things that impacted him, influenced his thinking, or helped him become more open to other ways of teaching mathematics.

> When I look back I have really asked those questions like "what's going on with children" and "what are we doing to children with traditional approaches" but I don't think I was really dissatisfied with what I was doing in my classroom, you know when my approach was more traditional, I just know that I was open to trying things and seemed to be searching for something and I started to explore things. [Interview data]

As Wesley continued to explore and implement new things over the course of a few years in his classroom, such as students working in groups more often and using manipulatives during the more frequent problem solving opportunities he was providing for them, he in turn was afforded more opportunities to listen to his students. It was this listening to his students, trying to understand and make sense of what they were understanding that infused his desire to continue to provide more of these kinds of opportunities as a part of his teaching.

Over a period of six or seven years Allan continued to be brought back to Wesley's school district to conduct mathematics professional development for both middle school and elementary school teachers. During these years the process of change and transformation in Wesley's ways of thinking about mathematics teaching and learning continued as did the emergence of new issues to be addressed and a variety of constraints that had to be considered.

Since those early years of perturbation and trying new things, Wesley has developed a classroom environment and community wherein students share their ideas, listening to one another, and are encouraged to come to consensus. Listening to students for Wesley not only played a major role in his transformation as a teacher but is now a natural and inherent part of his interaction with his students.

> One of the things that was really important and still is, I just don't think about it as much anymore because I just do it, I think, is listening to the students. Back when I was really trying things out and searching for problems it was really helpful and important to listen to the students while they worked on problems. I would try to understand what they were understanding and what they didn't have figured out. [Interview data]

For Wesley this kind of listening, listening to determine what the students are making sense of, is more than just listening for assessment purposes, for asking questions, or for even selecting the next task. It is listening to participate, to be engaged in the problem solving and in the community with his students. Wesley believes that this kind of listening, an active or engaged listening, is essential for his students to fully participate in the community he strives to develop in his classroom.

Discussion

Rather than being the end product of his attempts to change from one pedagogic approach to another, what happens in Wesley's classroom today is the expression of his beliefs about mathematics teaching and learning wherein a way of communicating with his students about mathematics is the learning environment in his classroom. While Wesley states that he follows a problem centered learning model what he does with his students is more than a model or a set of steps that someone else could follow to create the same thing, it is an orientation about what is mathematics and what it means to teach and learn mathematics, one that views the classroom as a community and the teacher as co-learner.

This study shed light on the inherent and integral role of listening in Wesley's transformation. Wesley is a participant in exploring mathematics with his students. Hermeneutical listening is part of his orientation about teaching and learning. He views teaching not as the act of telling and learning as a not as a sequence of actions but rather understands and views learning "in terms of an ongoing … dance" (Davis, Sumara, and Kieren, 1996, p.153), wherein "individual and collective meanings are seen to evolve in the course of classroom interactions" (Cobb, Jaworski, and Presmeg, 1996, p. 15). Teacher and students are involved in the unfolding of the curriculum as knowledge emerges as meaning as their focus shifts from teaching or the learning of "things" to "that which is among them." Wesley hermeneutically listens to his students: the listening occurs so that he can become "a participant in the exploration of … mathematics" (Davis, 1997, p. 369). Listening for Wesley infused the unfolding process of his transformation and is now an integral dynamic of his emergent mathematics curriculum. Each day Wesley actively listens as one who is participating in a conversation; a mathematical conversation and discourse that evolves and emerges in his classroom with his students.

jcstore@uncg.edu

Sarah B. Berenson
University of North Carolina at Greensboro
sarah_berenson@uncg.edu

We noted fifth grade students' progress in making generalizations that related the independent and dependent variables and justifications that considered the global context of the pattern finding tasks during a 3-day teaching experiment. Since such development is at odds with previously reported research, we focused on teachers' discursive practices that co-constructed students' development of reasoning. Using Stein et al.'s (2008) framework, we found that anticipating, monitoring, connecting and purposefully sequencing students' responses co-constructed students' development of mathematical reasoning.

Introduction

Literature shows the need for students to develop fluency in mathematical reasoning (Martin & Kasmer, 2010; Yankelewitz, Mueller & Maher, 2010). We operationally define mathematical reasoning in this study as making and justifying inferences in pattern finding activities. Students' inferences according to Lannin (2005) can be classified as recursive or explicit. Recursive generalizations use the term-to-term change in the dependent variable to find unknowns. Explicit generalizations relate the input and output values and enable calculation of outputs given n inputs. Sowder and Harel (1998) classified justifications as externally based schemes, empirical and analytic. With externally based schemes, students do not show ownership of the justifications but instead refer to an external source. Empirical schemes show students' ownership of the justifications but do not regard the generality of the context. Analytic justifications consider the generality of the mathematical task's context.

Fluency in mathematical reasoning serves a lot of purposes in mathematics education. For example, it supports conceptual understanding and retention of students in advanced mathematics classes (Martin & Kasmer, 2010; Horn, 2008). Despite such importance, research has shown that most students have difficulties reasoning mathematically (Ellis, 2007; Lannin, 2005). These difficulties were observed in Lannin's (2005) study with sixth grade students and Ellis's (2007) study with seventh grade students where by students tended to make recursive generalization with ease in contrast to explicit generalizations. They also tended to make justifications that did not consider the general context of mathematical problems.

In this study, we observed that students developed their mathematical reasoning with more ease than reported in previous research (Lannin, Baker & Townsend, 2006). We classified the generalizations as explicit or recursive (Lannin, 2005). The percentages of students using each class of generalization are presented in Table 1 and indicate that students tended to use explicit generalizations by the third day of our teaching experiment. They also progressed to using empirical and analytical justification schemes (Sowder & Harel, 1998), with more students using the latter as in Table 2. Since it is a challenge to support development of mathematical reasoning, the objective of this study is to explore teacher's discursive practices that co-produced such development of mathematical reasoning as presented in Tables 1 and 2 that is at odds with previously reported studies.

Table 1: Percentage of Different Generalizations Expressed by Fifth Grade Students

Generalization strategy	**Task 1**	**Task 2**	**Task 3**
Recursive	69.6	30.7	8.9
Explicit	30.4	69.3	91.3

Table 2: Percentage of Different Justification Schemes Used by Fifth Grade Students

Justification strategy	**Task 1**	**Task 2**	**Task 3**
Externally based schemes	13.0	6.2	0
Empirical schemes	39.1	43.8	7.7
Analytical schemes	47.8	50.0	91.3

Theoretical Framework

Our perspective on learning which informs this study is that individuals learn as they participate in communities that enable them to internalize the cultural norms and appropriate the cultural tools that may modify their abilities and dispositions as learners (Claxton, 2002). The theoretical and methodological implication of this view is that, we needed to pay attention to students' assessed mathematical reasoning and the context that may explain those outcomes (Carlone, Frank-Haun & Webb, in press). As such, we addressed the research question, what are the discursive practices that co-constructed students' development of mathematical reasoning during this teaching experiment? We employed Stein et al. (2008) framework as our analytic lens to study the classroom elements that co-constructed student's development of mathematical reasoning. Stein et al.'s framework afforded us the discursive tools with which to discuss the teachers' pedagogical practices and reasoning. According to Stein et al., the following practices support productive discourse.

Anticipating Students' Responses

Anticipating is the expectation a teacher needs to have about students' possible interpretation of the problem, representations, solution strategies and their levels of sophistication. It is therefore necessary for teachers to have knowledge of students' thinking and different approaches to the tasks they give to students.

Monitoring Students' Responses

To monitor students' responses, the teacher moves around the classroom as students work on their tasks to note strategies and solutions and to listen to assess students' understanding. The teacher might also ask probing questions at this phase to help connect students' reasoning to the major concepts.

Purposefully Selecting Student Responses for Public Display

A teacher selects strategies, ideas and representations to display during class discussion. The decisions might be based on the mathematical ideas that are in the selected students' work. It is important at this phase for teachers to note their patterns of selection to ensure all students and different ideas are given attention in the class.

Purposefully Sequencing Student Responses

After selecting the responses that will be used during class discussion, a teacher also needs to make decisions of the sequence the responses will be presented. This sequence might be dependent on the teachers' knowledge of the students' thinking and the objective of the lesson. The sequence of students' responses affects coherence of the lesson, students' depth of understanding and has ability to clarify misunderstandings.

Connecting Student Responses

Class discussion presents a chance for teachers to guide students to connect ideas and strategies so as to modify their own ideas for better understanding. This can be accomplished if students evaluate each other's arguments and ideas. Teachers who carefully use questioning strategies and sequencing of tasks also provide helpful connections. These connections assist students' identification of the consequences of using different strategies.

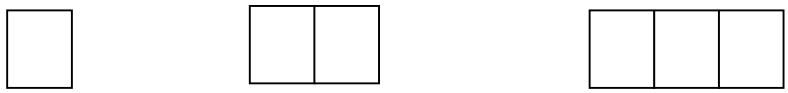
According to Stein et al. (2008), this model integrates the teachers' practices that were discussed separately by different authors. Stein and colleagues also argue that the ability to use these five practices is dependent on teachers' understanding of students' reasoning and the teachers' current thinking. This study contributes to this model and mathematics education by discussing how these practices, integrated as in this model, are enacted in an elementary mathematics classroom and the teachers' thinking that might take place in making the decisions at each of these phases. This study also associates this model to students' development of mathematical reasoning. Additionally, it contributes to ways in which teachers may balance the support of discourse and mathematical reasoning, which has been reported as challenging (Baxter & Williams, 2010; Sherin, 2002).

Methodology

Data for this study were collected during a three-day teaching experiment. The lesson for each day took about 90 minutes. The participating students were 23 fifth graders at a science magnet elementary school in the South Eastern US. One of the researchers, referred to in this study as teacher/researcher, replaced the classroom teacher during the teaching experiment. Other researchers assisted in collecting video and audio data. Field notes and student artifacts were collected at the end of each lesson as sources of data. The teacher/researcher's reflections on her reasoning behind the observed discursive practices were also part of the data collected.

Students worked on pattern finding tasks. Task 1 involved trains of square tables as modeled in figure 1. Task 2 involved trains of triangle tables and task 3 involved trains of hexagon tables. They were asked to find the maximum number of people that would sit around a train of one, two, three and 100 tables given that only one person can sit on one side of each smaller table. They organized their data using t-tables, observed the patterns, made and justified their generalizations. Small group discussions were followed by whole class discussions. We used Stein et al. (2008) framework to analyze the data.

Figure 1: Task 1



Results

Anticipating Student Responses

The teacher/researcher explained in episode 1 what she anticipated students' strategies and reasoning to be.

Episode 1

Teacher/Researcher: I have used this task in two previous teaching experiments and several graduate classes. I have learned from the first teaching experiment that triangle tables are difficult for students to find an explicit rule so I like to start the pattern block tables with squares. Generally students at all levels start off with a recursive strategy to find the pattern…

From this episode, her previous experience with teaching the task helped in anticipating what the students' responses might be. What she anticipated influenced her planning stage as she made decisions on how to sequence the tasks for optimal reasoning by students. She also anticipated that the students might not have had a lot of experience with finding patterns. As such, she planned to spend enough time to introduce pattern finding activities and the language (e.g. building models, input/output tables, and justification, and rules or generalizations) associated with such activities.

Monitoring Students' Responses

The teacher/researcher walked around the classroom to note students' responses as students worked on the tasks in pairs. This gave a chance to students to ask for clarifying questions about the tasks and for the teacher/researcher to ask probing questions to further students' reasoning. Episode 2 is one example where the teacher/researcher was walking around the classroom as students were working on justifying their rules about how many people can sit around a train of triangle tables.

Episode 2

Teacher/researcher [to Jane and Freddy]: So, have you figured this out yet (how to justify t+2 = p as a rule for finding number of people who can sit around a train of n triangle tables)?

Jane: The two comes from the two more people.

Freddy: From the two sides of the –

Teacher/researcher: Which two sides?

Freddy: Actually from the two sides of the triangle that you add to.

Teacher/researcher: Okay, build a model and show me where those two are.

By asking questions to the students, the teacher/researcher got a chance to note students' reasoning and responses. Other questions were meant to challenge students to move beyond the recursive rules they expressed to developing explicit rules. Monitoring students' responses also informed the teacher/researcher on how to effectively progress with the lesson. The following episode 3, whereby the teacher/researcher was thinking aloud during the lesson on the first day of the experiment is one example of such a case.

Episode 3

Teacher/researcher: I'll wait until they build their models and then we'll talk about the T table or the input/output table.

Although she planned to spend ample time discussing how to collect data into input/output table, monitoring students' responses redirected that plan. In her reflection she explained "I decided to abandon giving directions on building the t-table. Brenda and Dan already understood how to collect their data." After noticing that some students already knew how to build input/output tables, we observed that she briefly discussed the tables. This was done to make sure each student in the classroom understood how to collect data using T charts and for the students to "learn how to collect data in a systematic manner."

Purposefully Selecting Student Responses for Public Display

Responses were selected for different purposes. The teacher/researcher repeatedly mentioned that she was selecting responses from students so as to give each student a chance to display their work and explain their thinking. Students' generalizations and justifications that were expressed differently or were different from or conflicting each other were selected too. She did this as she communicated that reasoning tasks can be approached using different strategies. This gave a chance to students to evaluate strategies and responses. It also created opportunities for students to adopt strategies and responses that made more sense to them.

Purposefully Sequencing Student Responses

During whole class discussions, she generally ordered presentations of students' reasoning from less to more efficient. According to the teacher/researcher, this was purposefully done to include more strategies and solutions for public display while simultaneously staging the students to notice how the strategies and tasks were related to each other. This approach supported mathematical argumentation, conceptual understanding and co-construction of ideas. An example of this was on the second day when students were justifying their rules. Becky explained that the rule n+2=p was valid for a train of triangle tables because every time 2 tables were being put together; the train was losing 2 sides that were previously available. The following argumentation and thinking in episode 4 followed.

Episode 4

Sam: … speaking of the way she said, you're not subtracting two, you're adding two.

Teacher/researcher: Oh, okay. Becky?

Becky: Yes?

Teacher/researcher: He said that you're (your rule is) not taking away, you're adding two to the number of blocks.

This argumentation based on students' perceptual schemes went on, bringing in new understandings. The teacher/researcher finally asked another student, Benny, with a different justification who explained that the rule t+2=p holds because "the plus 2 comes from the end sides of the triangle table (train)" and number of people is constantly equal to number of tables in that pattern.

In general, students' generalizations were also purposefully sequenced from recursive to explicit during whole class discussions. This was achieved by having whole class discussions in multiple phases. There were mainly three phases. Phase 1 discussions were after or when students built the models and collected data into the input/output tables. Phase 2 was after students explored patterns and were prompted to respond to questions that could be answered using recursive rules. Finally, whole class discussions were held after students were challenged to develop explicit rules. This practice created a context in which recursive rules were presented before explicit rules.

Connecting Student Responses

Connecting different students' responses. Whole class discussions at each critical phase of the tasks (modeling and data collection, generalizing recursive rules, generalizing and justifying explicit rules) afforded students opportunities to connect their reasoning to other students' reasoning. Similarly, teacher/researcher constantly encouraged students to evaluate each other's argument. Episode 5 is one instance on the first day of the teaching experiment as students were working on task 1 where the teacher encouraged students to reason as to why their classmates' rules were valid or not. In this episode, Brenda presented a rule for finding number of seats available on a train of n square tables and the other students evaluated why that rule could be valid. We observed that this approach encouraged students to incorporate other students' strategies into their own. For example, after one student used a geometric representation to justify the rule 2n+2 =p for a train of square tables, most students incorporated this representation into their explanations.

Episode 5

Brenda: Multiply the tables times two and then add two to find the number of chairs.

Teacher/researcher [to the whole class]: Think about that (rule) one more time, does that work?

Stan: Yeah.

Teacher/researcher: How do you know it works?

King: Because T (input) times two every time is two less than C (output) and if you add two plus T it works.

Teacher/researcher: And Sam, what did you say?

Sam: It does work.

Connecting responses across tasks. Several attempts were made by the teacher/researcher to connect students' reasoning across tasks. Her choice of isomorphic tasks was one attempt. Furthermore, during the lessons she asked questions that encouraged students to reflect on previously worked out tasks (as in episode 6) as they reasoned about the tasks they were working on. This approach supported development of reasoning as evidenced in students' reasoning in episode 7 that followed the teacher/researcher's prompt.

Episode 6

Teacher/researcher: Alright, most of you have some great ideas. Most of you are thinking very hard and working very hard on this and I'm going to give you a hint…. Remember on the first day when we did squares (Task 1)? And you said there would be a hundred tables here (showing a model developed by a student)? And that meant that there were hundred (seats) on the top and a hundred (seats) on the bottom and one on each end? That was a hint. (Use it) to think about the hexagons.

Episode 7

Jane: So, a hexagon has two sides (on the top), so it has two hundred on each side (top and bottom).

Teacher/researcher: Right.

Jane: And two hundred times two is four hundred plus the two on the ends is four hundred and two. Is that right?

Discussion

Stylianides and Ball (2008) recommend that teachers need to have content knowledge for teaching mathematical reasoning. Such knowledge includes knowledge about reasoning tasks and the type of reasoning that tasks can support. To recap, the teacher/researcher anticipated generalization and justification about a train of triangle tables to be more challenging since she used this task with undergraduate and graduate students. Knowledge about the tasks and students' reasoning were important in her expectation of students' responses and consequently planning. Teachers can prepare at the anticipation stage by trying out different strategies that students might use or keep a variety of student work to review when tasks are repeated with other students. Keeping such a record helps the teacher to be flexible if student responses are different from what the teacher anticipated.

Since past research (Lannin, et al., 2006) reports that students develop recursive generalizations with relative ease, discussing recursive generalizations is one way to include responses from more students during whole class discussions. Discussing recursive generalizations before explicit generalization potentially supports students' ability in using both types of generalizations while simultaneously appreciating the usefulness of explicit generalizations. Also, some mathematical tasks in their curriculum may require students to use recursive generalizations.

There is substantial research (Cobb, Gresalfi & Hodge, 2009; Mueller, 2009; Store, Berenson & Carter, 2010) that supports the view that discussions nurture mathematical reasoning. We add to this body of research, that teachers need to purposefully select responses for public display. Selection of responses may be based at including all students' thinking in the discussions and sequencing responses to connect to the goal of the lesson. Selecting responses that are expressed differently and correctly may support students' appreciation of mathematical reasoning as a discipline that can be approached using different strategies. Purposeful selection of responses that are contradictory also creates opportunities for the classroom members to reflect on their thinking and develop their reasoning (Komatsu, 2010).

It is important to emphasize the nonlinearity of the sequence of these practices. As mentioned, the discussions were held in different phases. On each phase, the teacher/researcher walked around the classroom to monitor students' responses and made decisions of what student responses should be displayed publicly, and how to sequence and connect displays of student responses.

DOES IT STILL "WORK": CGI IN A CONTEMPORARY CA HIGH-POVERTY DISTRICT

Melissa Soto
University of California-Davis
mmsoto@ucdavis.edu

Cathleen Alexander
University of California-Davis
cmalexander@ucdavis.edu

Given the dynamic landscape of mathematics instruction, programs that were once deemed effective need to be periodically examined to insure that their benefits continue to be realized. This study focused on an implementation of Cognitively Guided Instruction (CGI) in an economically disadvantaged school district serving a large percentage of English Language Learners. This setting and instructional context was considerably different from those of earlier studies of CGI's effectiveness. Results of a written test administered in the spring of each school year showed that the more CGI training a teacher had, the more story problems their first graders could solve.

As Slavin and Lake (2008) pointed out "the mathematics performance of America's students does not justify complacency. In particular, schools serving many students at risk need more effective programs." In their review of research on effective elementary school mathematics programs, they claimed, "programs found to be effective with any subgroup tend to be effective with all groups." On the other hand Raudenbush (2005) cautioned that interventions do not always "work" for every population of children so research should include clarifying the subsets of children who benefit from specific interventions. In Slavin and Lake's review a large proportion of the studies they examined were conducted before 2000. The demographics of the country have changed dramatically in the last ten years especially with the influx of English Language Learners into schools, and the conditions of mathematics instruction have changed drastically for teachers. The programs found to be effective in the 1980s and 90s may be more difficult to implement with the advent of the stress on standardized testing in recent years. Given the dynamic landscape of mathematics instruction, programs that were once deemed effective need to periodically be examined to insure that their benefits continue to be realized, and they need to be researched with different populations of students to determine their generalizability.

Theoretical Framework

Our study focused on one of the programs, Cognitively Guided Instruction (CGI) (Carpenter, Fennema, Peterson, Chiang, and Loef, 1990), that Slavin and Lake(2008) deemed to be effective, and we explored the degree to which this program was effective in 2007 – 2010 in an economically disadvantaged school district serving a diverse population of students including a sizeable number of English Language Learners. While descriptive studies indicate that CGI has been implemented with great success in diverse settings including high-poverty predominantly African-American schools in Prince Georges County, Maryland (Carey, Fennema, Carpenter & Franke, 1995) ; Oneida Indian Reservation schools in Wisconsin (Henkes, 1998), and predominantly Hispanic schools in the Los Angeles area (Franke & Kazemi, 2001), these studies did not include student achievement data. The only study with achievement data and a comparison group documenting CGI's success with economically disadvantaged students of color is over 15 years old (Villasenor & Kepner, 1993). We felt the need to re-establish CGI's effectiveness with the kind of research-based evidence valued by decision makers at this point in time.

The CGI project demonstrated that when teachers learn about children's mathematical thinking, teachers change their mathematics instruction to address the mathematical development of the individuals in their classroom, and their students outperform children from control classrooms on measures of problem solving (Carpenter, Fennema, Peterson, Chiang & Loef, 1990). In CGI workshops teachers learn about a framework describing the relationship between the difficulty of word problems and the level of sophistication indicated by children's solution strategies. The framework assumes that teachers feel free to choose problems for their students to solve and can take the time to discuss solution strategies with them. Teachers in our study were facing more constraints than teachers in previous CGI studies so it remained to be seen if their students would benefit from their participation in CGI professional development in the same ways as students in previous studies had. One of the findings from the longitudinal CGI study indicated that teachers' knowledge of CGI developed over time, with some teachers taking up to three years to become effective CGI teachers (Fennema, et al., 1996). Teachers with less freedom to experiment with using story problems in their classrooms, might take more time to become effective CGI teachers than teachers in previous studies, therefore we looked for a dosage effect to see how the number of years of a teachers' participation with CGI affected their students' achievement.

The research question guiding our analysis was:

What are the differences in first graders' problem solving performance according to the number of years their teachers have participated in Cognitively Guided Instruction professional development?

Methods

Professional Development Format

The project took place over a three-year period. The teachers attended meetings once a month afterschool. They also had three days of training each summer. The focus of all meetings was children's mathematical thinking. The CGI problem type and solution strategy frameworks were developed early on and were revisited frequently. Teachers were videotaped interviewing three of their students twice a year and these videotapes were shown and discussed in meetings. Teachers engaged their children in problem solving in their classrooms and brought student work to meetings to analyze and discuss. One of CGI the facilitators visited each teacher's classroom once a month to observe a problem solving session and discussed her observations of children's mathematical thinking at the meetings.

Setting

The professional development took place in one elementary school district with five elementary schools. The majority ethnic group in the district was Latino (37%) followed by Asian (19%), White (16%) and African American (15%). Eighty-six percent of the students received free or reduced price lunch and 43% of the students were designated as English Language Learners. Teachers in the district felt pressure to increase student test scores to meet the No-Child-Left-Behind Adequate Yearly Progress targets. Among the district norms were daily timed facts tests and close adherence to the mathematics textbook.

Design of Study

The data for this analysis came from the evaluation component of the CGI professional development project. As in many projects of this kind, during our three-year project the district had budget issues such that some of the teachers who began participating with us lost their positions by the third year of the project. We had to alter our research plan to accommodate this change. While the research design that we ended up with and describe here is not ideal, we felt that the data merited dissemination nonetheless.

To provide a comparison group we employed a delayed treatment design. Teachers at two of the schools began participation in the first year of the program and teachers from two other schools joined professional development in the second and third year of the program.

We collected two sets of data described in more detail below, a written test given to all first graders in the district and an interview done with a random sample of six children from each classroom. Timeframes and participants in these two data sets are distinct and will be discussed separately.

Written Test

In late May of each school year, all of the first graders in the district took a written test administered by their classroom teacher. The test consisted of 4 free-response story problems (see Table 1). Teachers read the problems aloud to students as needed, and children were told that they could draw a picture or use their fingers, blocks or equations to solve the problems.

Table 1. Story Problem Test Items.

Separate Result Unknown	Maria had 13 balloons. 5 balloons popped. How many balloons did she have left?
Join Change Unknown	Juan has 6 baseball cards. How many more baseball cards does he need to collect to have 14 altogether?
Multiplication	Sam has 3 packs of gum. There are 6 pieces of gum in each pack. How many pieces of gum does Sam have altogether?
Compare Difference Unknown	Lee has 12 pennies. Luis has 7 pennies. How many more pennies does Lee have than Luis?

*Participants***.** First graders taking the test had teachers with various levels of experience with CGI ranging from no experience to three years of experience. Table 2 shows the number of children and classrooms associated with each of the levels of CGI experience.

Table 2. Numbers of children and classrooms for each level of CGI experience

	No Experience with CGI	Teacher with 1 year of CGI	Teacher with 2 years of CGI	Teacher with 3 years of CGI
Number of classrooms	14	12	6	5
Number of children	284	238	115	106

Problem Solving Interviews

First graders worked one-on-one with trained interviewers in the fall and spring of the first grade in the second and third year of the project to solve story problems (see Table 3).

Interviewers read the problem out loud to the children and encouraged them to use any tool that they needed to solve the problem. The interviewer read the problem as often as the child needed. When a child stated a number, the interviewer asked the child if this was their answer, and if it was elicited an explanation by asking, “how did you get that answer?” All children were given the first three problems. If children were successful on two of these, they were given the other two problems.

Table 3. Story Problems for Interview

Separate Result Unknown (SRU)	The bear had 10 cookies. He ate 3. How many did he have then?
Multiplication	Robin has 3 bags of cookies. There are 5 cookies in each bag. How many cookies does she have?
Join Change Unknown (JCU)	You have $7. You want to buy a game that costs $11. How much more money do you need to earn so that you will have enough for the game?
Partitive Division	Four kids are sharing 12 candies. How many candies should each child get?
Compare Difference Unknown (CDU)	You have 12 balloons. Your friend has 7 balloons. How many more balloons do you have than your friend?

Participants. First graders participating in the interviews were in classrooms with teachers with various levels of professional development (see Table 4). Children were randomly selected in the fall of the school year and a few of these children left the district during the school year so were not available for interviews in the spring.

Table 4.

	No Experience with CGI	Teacher with 1 year of CGI	Teacher with 2 years of CGI	Teacher with 3 years of CGI
Number of classrooms	4	6	6	5
Number of children	24	27	30	26

Data Analysis

For both the Written Test and the Problem Solving Interviews, students received one point for every correct answer, one half if they used a correct strategy but miscounted, or zero points if they incorrectly solved the problem. Total scores were computed, analyzed, and descriptive and inferential statistics are discussed here. For the Written Test, a one-way analysis of variance (ANOVA) was conducted to determine if the mean student scores for each CGI experience group were statistically different from each other. Because there were four groups that represented the number of years of teachers’ CGI experience, a Scheffe Post Hoc test was performed to determine which groups performed significantly differently from other groups. For the Problem Solving Interviews, a one-way analysis of covariance (ANCOVA) was conducted to determine if the mean scores for each CGI experience group were statistically different while using the students’ pretest scores as a covariate.

Results

Written Test

The longer the teachers had participated in the CGI professional development, the higher their students' scores on the written test were. As is illustrated in Table 5, the mean scores for students whose teachers had three years of CGI were almost one point higher than the mean scores of children whose teachers had no CGI training.

Table 5. Mean Performance on Story Problem Written Test

Teachers' Experience with CGI	Mean number of items correct (4 possible)
0 years (n=284)	1.76
1 year (n = 238)	2.18
2 year (n = 115)	2.29
3 years (n = 106)	2.6

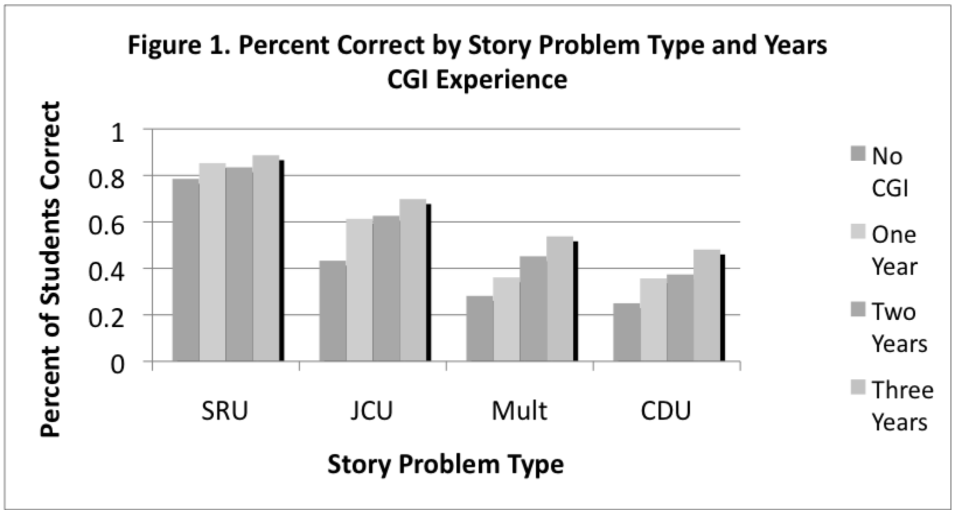
Table 6 summarizes the results of the Scheffe Post Hoc test of the differences in means for the written test. Students with teachers who had one or more years of CGI experience, scored higher than those students with teachers who did not participate in the CGI professional development program. Those students with teachers who participated in the CGI professional development for three years scored higher than those students with teachers who only participated one year in CGI experience. There were no differences found in student scores for teachers who participated one or two years and two or three years.

Table 6. Difference in students' mean performance on written test according to Teachers' Dosages (number of years of CGI training)

	0	1	2	3
0	X	-.43*	-.53*	-.85*
1	.43*	X	-.10	-.42*
2	.53*	.10	X	-.32
3	.85*	.42*	.32	X

* = statistically significant at $p < .05$ level

An examination of students' performance on the written test by problem types (see Figure 1) shows that teachers' experience made a small difference for students' performance on the Separate Result Unknown problem (SRU); while one year of experience made the biggest difference for the Join Change Unknown (JCU). For the other two problems [Multiplication (Mult) and Compare Difference Unknown (CDU)] the longer the teachers participated in CGI, the greater percentage of their students were able to solve these problems.



Problem Solving Interview

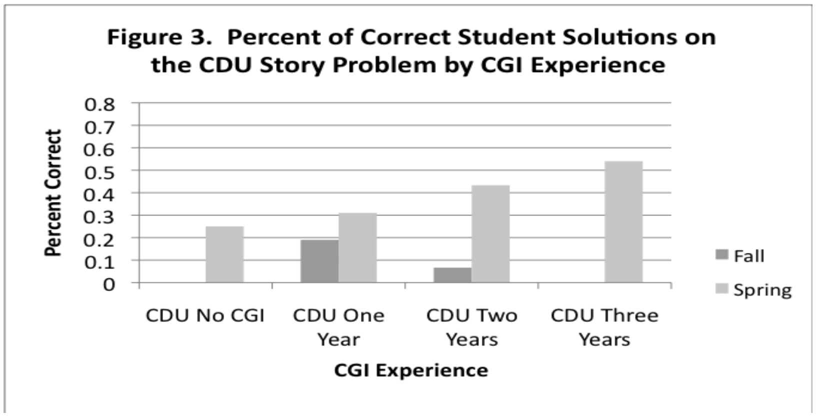
First graders' performance on the problem solving interview varied in the fall with children whose teachers' had no experience with CGI having the lowest performance (see Table 7). This can be explained by the fact that as kindergarteners these children had been with teachers without any CGI training while the children in the other groups tended to have been in kindergarten classrooms with teachers who had been involved in the CGI training. This fact does not account for the fact that in the fall children in first year teachers' classrooms outperformed children in the other classrooms, and we do not have an explanation for this beyond being due to chance. The difference between the fall and spring means were statistically significant for all four groups.

Table 7. Children performance on Problem Solving Interview (highest possible score 5)

Teachers' Experience with CGI	Fall Mean Performance	Spring Mean Performance	Difference in Mean (Spring – Fall)
No CGI n = 24 children	.75	2.38	1.68*
One Year n = 27 children	1.46	2.74	1.28*
Two Years n = 30 children	1.22	2.90	1.68*
Three Years n = 26 children	.94	2.96	2.02*

Table 7 shows that children in all the groups tended to improve in their performance from the fall to spring with the children in classrooms of teachers with three years of CGI experiences tending to improve the most. Although the students that changed the most were those who had teachers with three years of CGI training, none of the comparisons between groups proved to be statistically significant.

An analysis of students' performance by problem type showed similar trends as the written test for the Join Change Unknown problems with success rates being higher for students in teachers' classrooms with at least one year of CGI experience and a steady increase in the percentage of children successful on the Compare Difference Unknown problems with each year of CGI training (see Figure 3). The Partitive Division problem had the lowest success rate for all groups, with the greatest success rate going from 25% for the No CGI experience group to 38.5% for the 3 years CGI experience group.



Conclusion

The results of the written test show that for this implementation of CGI in this particular school district, children tended to be more successful solving story problems when their teachers had CGI training. Moreover their seemed to be a dosage effect because as children's teachers had more CGI experience, more of their students were able to solve problems. We propose two explanations for differences in student achievement. First, we posit that participation in CGI training led the teachers to do more problem solving with their students. This has been the case in previous CGI studies (Carpenter et al., 1990, Fennema et al., 1996). While we did not have the resources to observe the teachers on a regular basis, their reports to us in the workshops support this assertion. In addition, they brought student work to our meetings so they were engaging their students in problem solving at least once a month.

The second explanation relates to our analysis of particular problem types showing that differences in overall success rates were due to differences in performance on the less conventional problem types. During CGI training, teachers learn about these problem types and the ways that children think about them. For example, they learn that children can readily solve Join Change Unknown problems but children do so using additive strategies rather then subtractive strategies. In our workshops the teachers readily picked up on the distinction between Join Change Unknown and Separate Result Unknown problems, and we posit that their students encountered this problem type more frequently than children whose teachers did not have CGI training. In addition when their students solved these problems, we posit that their teachers supported them in solving the problems in ways that aligned with an additive interpretation rather than imposing a subtractive interpretation on to the children. Compare Difference Unknown problems tend to be the hardest problem type for students (Fuson, Carroll & Landis, 1996) and our data suggest that as teachers had more opportunities to ponder this problem type over time, they became more effective at facilitating their students in solving it.

While the data show that teacher participation in CGI training affected student achievement, first graders in this sample did not perform as well as kindergarteners in Wisconsin in 1993 (Carpenter, Ansell, Franke, Fennema & Weisbeck, 1993). In that study the majority of the children were native English speakers and the teachers had a great deal more discretion over instruction than teachers in our study. Teasing apart which factors, language issues or instruction, might account for the difference in our students' performance as compared to that of the 1993 sample is impossible to do with the data that we have. The teachers in our group reported feeling limited in the amount of time they could devote to problem solving because of the emphasis on getting through their textbook. Their use of timed tests and other drill activities may also have affected children's beliefs about mathematics making them more hesitant to solve problems using manipulatives or drawings. Insuring problems were comprehensible to English Language Learners through careful wording and choice of context, added to the complexity of implementing CGI in this setting. Given these differences in the conditions of implementing CGI, we felt that the students' performance was encouraging. The added complexity of this setting suggests that teachers may take longer to become effective in employing CGI in their instruction than did the teachers in previous studies.

We continue to work with teachers in the district and are now working with the 3rd and 4th grade teachers who are teaching the cohort of students who participated in this study. If there are cumulative effects of having CGI teachers over time, we will be able to demonstrate these effects with case studies of some individuals, many of who are English Language Learners.

We acknowledge that our sample size is small and our study inadequate to make strong claims, nonetheless we do think the data show positive effects for CGI and suggest that its benefits generalize to economically disadvantaged English Language Learners in this time of heightened accountability. We hope that these tentative findings can be supported with a larger, more robust study of implementation of CGI with this student population.

INVESTIGATING A FIFTH-GRADE MATHEMATICS TEACHER'S PRACTICES IN RELATION TO HYBRID SPACE

Jennifer Cribbs
Clemson University
jdshipl@clemson.edu

Sandra Linder
Clemson University

This study adds to current literature on hybrid space with a focus one fifth-grade mathematics teacher. The researchers conclude that the teacher's instructional practices allowed her to create opportunities for a hybrid space to emerge in her classroom. The framework developed in Barton and Tan's (2009) work in science is applied to a mathematics classroom to investigate the use funds of knowledge and Discourses. Evidence from this case study found that two themes were present in the classroom: family funds of knowledge and Discourse and peer funds of knowledge and Discourse. The implications of this study could help teachers and researchers better understand how to motivate students concerning mathematics.

Purpose

The purpose of this study is to examine the instructional practices of one 5th grade mathematics teacher through the lens of hybrid space. Hybrid space is a classroom environment where teachers can engage students in learning by bridging the mathematics content with the knowledge and background of their student (Moje, Ciechanowski, Kramer, Ellis, Carrillo, & Collazo, 2004). Investigating the teaching methods of one teacher and funds of knowledge and Discourses in a classroom can inform researchers and practitioners on how to make learning applicable to students' lives (Barton & Tan, 2009). A case study was used to answer the research question: How can teacher practices create a hybrid space in a mathematics classroom?

Perspectives

The National Council of Teachers of Mathematics (NCTM) acknowledged the importance of discourse in teaching mathematics through principles and standards that call for teachers to build on discourse in the classroom (NCTM, 1991, 2000). Cobb and his colleagues (1997) discuss the concept of discourse and theorize that it can provide support to students' mathematical development that is more consistent with reform shifts to have students engage in verbalizing their mathematical reasoning. Discourse is also an important construct in Gee's (2000) work on identity, which defines Discourse as a "way of being 'certain kinds of people'" (p.110). Their "way of being" might entail being a math person or being a member of a sports team. Importantly, Gee's definition of Discourse encompasses the verbal discourse NCTM recommends but also expands to include how students interact with the content and express themselves in relation to the content (Barton & Tan, 2009). For example, students might interact with the content of mathematics by discussing what a meter is and how it is defined, but they may also choose to create representations of a meter with physical objects or use tools to assist them in their understanding of the mathematics content. Students may even become to see themselves as mathematics experts and an important contributor to mathematical understanding in the classroom.

Hybrid space is a classroom setting where a teacher fosters students' participation so that they become engaged with the content in a meaningful way (Moje et al., 2004). Barton and Tan (2009) further define a hybrid space as "a supportive scaffold that links traditionally marginalized funds of knowledge and Discourses to academic funds and Discourse" (p.52). Academic funds in that definition refers to the mathematical content. Funds of knowledge in their view refers to the base of knowledge that students have from their experiences and cultural backgrounds (Gonzalez & Moll, 2002). Students may enter a classroom with minimal knowledge of how to add fractions, but they may have used fractions in cooking or dividing candy among siblings. Teachers can use a hybrid space as a bridge between the students' previous funds of knowledge and academic funds of knowledge to build on the students' Discourse with mathematics. It is a combination of funds of knowledge and Discourse that is integral in creating a hybrid space. Flessner (2009) stressed the importance of creating an environment that was conducive for creating a hybrid space. His classroom allowed students to feel "safe, respected, and confident" in addition to being "contributing members of the classroom community." (Flessner, 2009, 432) In this view, it is important that a teacher allow students to contribute their own knowledge about content. A teacher need not be the sole supplier of expertise. Teachers can add contextual content that relates to student experiences to provide opportunities for a hybrid space in the classroom. For example, a teacher can present problems that relate to real life situations such as games the students play or provide materials that the students have experience with such as measuring cups or scales. This view is also discussed by NCTM which calls for the use of contextual methods of instruction so that students learn mathematics that is in relation to real world scenarios (NCTM, 2000). Whereas contextual learning is an important part of reform in education, Boaler (1993) found that contextual problems are not necessarily increasing student learning because they may not incorporate realistic, real world problems that students were able to make their own. This idea emphasizes that it is important for context to relate to the students' experiences and backgrounds so that they are engaged in meaningful Discourse.

The present study examines how creating a hybrid space in a classroom can allow students to build on their Discourse in mathematics through the use of funds of knowledge and Discourse. Barton and Tan (2009) created a framework for viewing a hybrid space in the context of a science classroom. This framework included four specific constructs: (a) family funds of knowledge & Discourse, (b) community funds of knowledge & Discourse, (c) peer funds of knowledge & Discourse, and (d) popular culture funds of knowledge & Discourse (Barton & Tan, 2009). Family funds of knowledge and Discourse refers to how students draw on their experiences of family life such as shopping trips or playing school with siblings to participate in classroom mathematics. Community funds of knowledge and Discourse relates to how students draw from their community such as their participation in their school or neighborhood community to participate in classroom mathematics. Peer funds of knowledge and Discourse is how students draw on their experiences with peers to help and support each other in learning mathematics such as validating each other's responses in class or showing concern for peer understanding. Popular culture funds of knowledge and Discourse refers to how students draw on their experiences with popular culture such as television or music to participate in classroom mathematics (Barton & Tan, 2009). This present study utilizes Barton and Tan's framework to examine a hybrid space in an elementary mathematics classroom.

Methods

This study came out of a larger study on student motivation in elementary mathematics (Linder, Smart, Cribbs, 2011). Based on the findings from the original study, it was determined that one teacher in an elementary setting in the Northwest region of South Carolina had students who displayed significantly higher levels of motivation than all other students in the school. This

5th grade teacher became the focus of the current study to determine what teacher practices might account for these results.

A case study analysis of this 5th grade teacher's instructional practices in mathematics was conducted in the spring of 2009. Data was collected through classroom observations and paired student interviews. Nine classroom observations were conducted, recorded, and later transcribed by a member of the research team. Student interviews were also conducted in pairs using a semi-structured protocol to get a better idea of how students perceived mathematics and their teacher in relation to mathematics. A member of the research team later transcribed the interviews. Data analysis included repetitive readings of all transcriptions and viewing of videos to create an initial theoretical explanation of what was occurring in the classroom. This theory was then strengthened by supporting evidence gleaned from the data collected (Yin, 2009).

The school that this study took place is a Title I school where 81% of the school population receives free or reduced lunch. The teacher observed taught four different classes through the course of the day, and interviews were conducted with 21 different students from these classes.

Results

Classroom Environment

It was apparent from the first observation that the teacher had a strong command of her classroom. She was firm and purposeful with her students and their activities, but she also nurtured students with a friendly and open demeanor. Even in the midst of noisy and mobile activities, the teacher maintained control and kept students on task. One of the defining characteristics to creating an engaging classroom was the teacher's constant questioning of students and challenging them to think about the content. She often engaged the students in discourse with her and with each other. The following interaction is an example of this discourse between the teacher and the students as they discuss weight. The students have been broken up into groups of 3 or 4. They have also been given a bag of popcorn, one for each group, to investigate together.

> Teacher: "…Now, I have a question for you, or several questions for you. What is a reasonable estimate for the weight of this bag of popcorn in pounds? What would be a reasonable estimate for that?" The teacher called on one student with her hand raised.
> Student: "One pound."
> Teacher: "Ok, Alice says one pound. Does anybody else have another…? You say one pound." The teacher pointed to a student at the front and then called on another student.
> Student: "Two pounds."
> Teacher: "Ok, two pounds …Ok, so we've got one pound, we've got two pounds, ok. What is a reasonable estimate for the weight of popcorn in ounces? Think about the estimate that you gave me and what would be a reasonable estimate in ounces? What would be a reasonable estimate in ounces?" Teacher called on another student who responded with 20 ounces.
> Teacher: "Ok, [student] says twenty ounces. What would you say?" The teacher called on another student. "He says sixteen. Why do you say sixteen?"
> Student: "Because it feels like a pound."
> Teacher: "It feels like a pound. Ok, why'd you say twenty?"
> Student: "Because it feels like a pound and it has some ounces left over."

The teacher continued the discussion by asking the students to give examples of what other objects might weight the same as the bag of popcorn. The teacher asked the students questions that were open ended and required them to explain their reasoning. The students were asked to interact with the content in the form of a bag of popcorn and also relate it to their own experiences. This type of interaction was seen repeatedly in classroom observations of the teacher.

When students were asked in interviews how they would describe their teacher, they stated that she was "smart", "funny", "helpful", and "a good teacher" among many other similar comments. In response to the question "Do you think [your teacher] thinks math is important?" two students stated the following:

> Student 1: "She like applies it to real life things…Like with geometry, like with like structures, how they need to be built. Like construction. How they need to be built just to stand."
>
> Student 2: "And sometimes in math like she compare (sic), like when she doing geometry, she compare it to real things in life. Like a rectangular prism as a cereal box. A sphere as a ball. She can explain it as to real life things."

It was through these methods of instruction along with the comments made by students in interviews that the researchers began to see a pattern that allowed for students to bridge the gap between the mathematics content being taught and their background. This concept will be discussed further in the next section through a framework of hybrid space.

Creating a Hybrid Space

Two of the four constructs from Barton and Tan's (2009) framework emerged through our analysis present in this study. These constructs are discussed below with reference to how they were present in the classroom with supporting evidence from student interviews. It is important to remember that the teacher was not intentionally creating a hybrid space but rather this space occurred spontaneously as a result of her teaching practices. Flessner (2009) discusses this idea by stating that it was only when he stopped trying to create a hybrid space that one occurred, and that it may be best for teachers to focus on creating the conditions that are conducive for a hybrid space.

Family Funds of Knowledge and Discourse

Family funds of knowledge and Discourse is related to the student's family life such as events or activities that were discussed by the students Barton and Tan (2009). In the first lesson that was observed, the teacher brought items from her house for students to compare and contrast. The essential question that was posted for the lesson was "What is capacity?" The teacher asked the students to make a decision as a class as to how items should be ordered from the smallest to largest capacity without looking at any labels. The students were presented with the following list of items: soda bottle, stomach medicine, marinating sauce, milk carton, throat spray, cooking oil, and olive oil. One student told the teacher that she thought the stomach medicine should go next as the teacher lined the items up from smallest to largest capacity on the desk. The teacher asked her to explain her rationale as detailed below.

> Student: "…because, like, when I take it, it's very thick."
> Teacher: "Ok, so, you based it on the thickness of it?" The teacher holds up the Pepto-Bismol
> Student: "Yeah. I based by how it looks."
> Teacher: "You didn't feel it."
> Student: "Like, yesterday I had to get some."

Teacher: “Oh, ok, ok, so, you’re using your knowledge that you might have used before by holding it, but let me ask you this…Ok, let me ask you this. You didn’t hold any of these other ones.”

Student: “No”

Teacher: “So how do you know that this [teacher holds up Pepto-Bismol] is heavier than this [holding up the throat spray]? “

Student: “I know the soda is heavier than all.”

Teacher: “So because it’s thicker, you think it is heavier? Ok, we’ll check all of that out.”

Another student is called on immediately after this discussion and relates her experience at home with capacity.

Student: “Um, in my house my sisters, they be trying to say that, well, they put two cups out. They put a big, it’s small and all thin and stuff, and they have a little small one. And they say the ones that’s small has more liquid inside it when it doesn’t.”

Teacher: “Ok, um, because it’s smaller, anyone have one of those, than something that’s taller?”

Student: “It’s wider.”

Teacher: “It’s wider. It could have more liquid than something that’s taller. And that’s true.”

The teacher discussed the idea of wide versus tall with the rest of the class, and the students began to order the items again. This interaction indicates that the teacher was open to the students sharing their experiences with capacity as well as discussing how it related to the current lesson. This helped the students to connect new concepts to previously developed understanding of the content.

During another classroom observation, the teacher put up the essential question “How are pounds and ounces used in the customary system?” Students were again asked at the beginning of the lesson to not only tell the teacher what they already knew about the topic but also encouraged to share how they used pounds in their lives. The discussion below began shortly after the lesson had started.

Teacher: “She said there are sixteen ounces in a pound. Where have you seen pounds and ounces used.” The teacher called on students to respond.

Student 1: “At the doctor.”

Student 2: “The store.”

Student 3: “Bi-lo”

Teacher: “Alright, at a store, Bi-lo, you said Bi-lo, and you’re weighing what?”

Student 3: “Like food.”

Student 4: “Like vegetables.”

Teacher: “Food, alright, wait a minute. One person at a time.”

Student 3: “Like food or vegetables.”

Teacher: “Ok, vegetables, ok. Where else?” The teacher called on another student.

Student 5: “At home.”

Teacher: “At home, how’d you use it at home?”

Student 5: “Like when you want to know how much rice you want to use.”

Teacher: “Ok” the teacher called on another student.

Student 6: “You can also use to how much milk you want to put in a cake.”

The teacher asked for a few more comments and then moved the discussion on to how to estimate weight by looking at an item. The teacher had brought bags of popcorn that was given to each group in the class. Students were asked to weigh the bag in their hands and later to compare it to other items in the class and in their book bags. Though conversations such as these can occur spontaneously in a classroom, the teacher fostered an environment where students could discuss mathematical concepts in relation to their own experiences. She also encouraged discussion and questions in the class. The brought household items for students to interact with and asked them to use their own items to help understand the concepts. Students were eager to participate and seemed to be excited about sharing their experiences.

Peer Funds of Knowledge and Discourse

In this study, peer funds of knowledge is related specifically to a subcategory that Barton and Tan (2009) refer to as a studenting Discourse. Studenting is how students provide peer support or specifically help each other with mathematics (Barton & Tan, 2009; Moje et al., 2004). This concept was evident in how students grouped together and helped each other to understand concepts. The following discussion between two students occurred during the lesson on capacity as described in detail in the previous section. The students are looking at a plastic measuring cup that the teacher has given them and asked the class to come up with inferences.

Student1: "Thirty-two equals is one quart and on this scale is always skipping fifty and one liter…"
Student2: "No, it's skipping like a hundred and fifty, I mean a hundred. Look."
Student1: "Yeah, yeah."
Student2: "It's skipping a hundred."
Student1: "One liter equals one thousand milliliters."
Student2: "It's skipping one hundred."
Student1: "Oh, I see. I already got confused with it."

Student 2 helps student 1 to understand what the intervals on the measuring cup indicate. During another observation, this type of studenting was observed again as one student struggled to understand a warm-up problem that was posted on the board at the beginning of class. The students are trying to determine what a flat diagram on the board will look like if it is folded to make a 3D image.

Teacher: "Ok, what shape does that make?" The teacher called on a student.
Student 1: "A cylinder"
Student 2: "The cylinder wouldn't look like that…one circle would be at the bottom. One circle is at the top." The teacher looked confused by the student's comment, so the student walked up to the board to show the teacher his explanation.
Student 2: "A cylinder would be like this. A circle would be here. The other circle would be right here, so when the wrap…" The student indicated with his hand what he was doing with the figure on the board.
Teacher: "Ok, what is it then?"
Student 2: "I thought it was a prism."
Student 1: "no"
Student 3: "Can I, can I…" This student goes up to the board to help the other student. The teacher lets them think through the problem together on the board.
Teacher: "We have a debate going on here."
Student 3: "If you put this side together with this side, it will make a round side like this. Then you pull this down like that right there and down there and it becomes a cylinder."

Student 2: "But the, but look, a cylinder it usually this circle's right here and this circle's right here."
Student 3: "These two circles up, and you fold it this way."
Teacher: "You probably, that's probably the way you're used to seeing it. Have you thought that this can actually be folded like this?" The teacher attempted to demonstrate the folding with her hands. "And then you're going to have this part here and that part here." The teacher is referring to the circles. "Can you see that?"
Student 3: "It's not a prism."
Student 2: "Oh, yeah"
Teacher: "Ok, guys. Ok, this is interesting. Do you see it now?"
Student 2: "Yeah, I see it."

This construct is repeated throughout the observations and supported in interviews. When two students were asked in their interview if they ever got to ask for help from friends in class, one student responded with "Like some people like didn't know how to do it. 'Cause I got a 100. And we had to help other people, so they could get a 100 too." In several of the interviews, students stated how they were concerned about their fellow peers understanding. When asked if they got to work in groups, one student stated the following.

"She [the teacher] placed us as in, like, she has like, I'm one of the high students. She has like certain high students with some people who don't learn as quickly and has some people who learns quickly. And then some people like for others to help."

It was clear from this comment that the students were engaged in helping each other through grouping. This pattern became even more apparent when the students were asked in an interview if their teacher would listen to them if they came up with a new strategy or idea in class.

Student 1: "Yes, she'll listen 'cause like we come up with new strategies to use in math. We come up with new strategies to see, try a strategy, um, like on a problem. And if she get it right, she'll say it's right. If she get it wrong, it's like, she'll tell you it's wrong. For some strategies, is like only on that problem. You a strategy on only that problem not on other problems like on the same subject, or the same thing."
Student 2: "She'll like accept it 'cause it might help…"
Student 1: "Other students."
Student 2: "Yeah, it might help other students. And like it might help her explain it better."

Not only were students supporting the idea of helping each other through sharing strategies, but they also felt that what they had to say was significant to the class. Both classroom observations and interviews revealed that students were concerned with each other's understanding and were willing to help each other. Their teacher often put them in groups or pairs in an effort to facilitate their learning and also encouraged them to explain their rationale to each other.

Discussion

This study suggests that a hybrid space can be created in a mathematics classroom and some of the constructs that have been found in other content areas are also present in a mathematics context. Two constructs from Barton and Tan's (2009) framework were evident after analyzing the data: family funds of knowledge and Discourse and peer funds of knowledge and Discourse. The reason why the other two constructs were not present could be that the teacher was not trying to create a hybrid space in her classroom. If the teacher had been intentional in her instruction for creating a hybrid space, all of the constructs in Barton and Tan's framework (2009) might have been present. The study was also limited in scope in that the lessons observed were over a short period of time. If observations were conducted over the course of the year, it is possible other constructs would be seen in the data. It is also possible that different constructs are more readily seen in different content areas as Barton and Tan's (2009) framework was based on a science classroom and that further research needs to be done to further investigate the framework for mathematics.

This study also presents the possibility that a hybrid space can contribute to student motivation in mathematics. The larger study that led to this case study was on student motivation. Students in this fifth-grade setting displayed higher levels of motivation for mathematics than all other K-5 students at the same school (Linder, Smart, Cribbs, 2011). The fact that students are active participants through Discourse in the lessons observed could contribute to their motivation. Sfard (2009) stated that "learning to speak, to solve mathematical problem or to cook means individualization of these activities, that is, a gradual transition from being an only marginally involved follower to other people's implementation to acting as a competent participant, with full agency over the activity" (p. 56). This statement could hint at the interplay that is occurring in the classroom.

The findings from this study suggest that teacher practices do impact the development of a hybrid space in a mathematics classroom. This study also suggests that a hybrid space in a mathematics classroom may provide a method of improving motivation. The Discourse that was present in this teacher's classroom shows a picture of how students are trying to make meaning of the mathematics content and add it into their funds of knowledge. Further research needs to be done to better understand the relationship between teacher practices and hybrid space as well as influence a hybrid space can have on student learning. It is useful to investigate these teaching practices in more depth and examine the long-term impact to student learning and motivation when they are members of a classroom that allows for a hybrid space to exist.

QUALITATIVE PROPORTIONAL THINKING AND TECHNOLOGY

Elena Fabiola Ruiz Ledesma
Escuela Superior de Cómputo. IPN
efruiz@ipn.mx

Patricia Camarena Gallardo
ESIME. IPN
pcamarena@ipn.mx

The research reported in this paper has a bearing on qualitative proportional thinking, for which technology is used; specifically an interactive computational program which supports the construction of the concept of proportion in a qualitative way is developed. The indicators of this concept are constructed and the ones of the development of qualitative proportional thinking, the design of didactic activities and their insertion in the interactive computational program is shown, as well as its implementation, to finish with the analysis and discussion of results.

Introduction

The development of proportional thinking is important since basic educational levels, as from it depend that children be able to comprehend and face everyday situations which are linked with the concept of proportion. At the same time, as it is established by XXX (2002) in order for *the student at basic level to be able to assign sense and meaning to proportion it is fundamental to develop his proportional thinking, both the qualitative and the quantitative*. That is to say, for the development of proportional thinking it is required, among others that the subject constructs the concept of proportion, and in order for him to be able to construct this concept it is required to have proportional thinking. In other words, there exists a bidirectional relationship between the mathematical concept of proportion and proportional thinking.

In order for a child to identify the proportional, in accordance with Piaget (1978), this should be made starting from the concrete to reach the abstract. Similarly, the construction of this mathematical concept is represented both at a qualitative level and at a quantitative one, which determines the proportional thoughts both qualitative and quantitative, respectively.

From another perspective, nowadays, within the educational contexts there exists the possibility of designing and developing technological materials of an interactive type. Whatever classroom experience can use electronic technology as mediation way, but it is necessary to value dimensions such as: objectives to be reached, organization of the themes which enable the development of the preferred contents to be included, learning activities and the evaluation both of the learning and the overall process.

On the other hand, the increment of technological materials is amazing; however, didactic strategies designed with theoretical elements are not always included. In the research being shown, in this paper, the educational theory named *Mathematics within the Context of Sciences* is used, by means of which the mathematical themes and concepts should be treated is such a way that they are linked to the environment, to everyday activities, to labor and professional competencies, as well as to the other sciences studied by the pupil.

From what has been described, a research has been dealt with whose problem is the construction of the concept of proportion and the development of proportional thinking both qualitative and quantitative, by means of didactic activities with electronic technology, in sixth grade children from elementary education. Since the research is so vast, this presentation only reports one didactic activity for the development of qualitative proportional thinking, as well as its implementation and analysis, which constitutes a partial research.

The objective of the partial research which is reported is to design didactic activities for the construction of the concept or proportion (in a qualitative way) and the development of qualitative proportional thinking, by means of an interactive computational program.

The supposition of research emerges from the fact that upon constructing or reconstructing the concept of proportion, there will be, to some extent, a bearing on the development of proportional thinking, for this report, on the qualitative proportional thinking.

Methodology

The design of the activities for the development of qualitative proportional thinking, by means of an interactive computational program, uses a methodology provided in the following three steps: 1. To determine the indicators associated with the construction of the concept of proportion (in a qualitative way), as well as the indicators associated with the development of qualitative proportional thinking (by means of the mathematical concept). 2. To design the didactic activities on the concept of proportion and their insertion in the interactive computational program. 3. To implement the interactive computational program and, to analyze and to discuss the results.

Theoretical Foundation

Mathematics within the Context of Sciences

The theory of *Mathematics within the Context of Sciences* establishes that mathematics should be presented to the student, at any educational level, through contextualized events, (Camarena, 2005, 2009). This theory conceives the learning and teaching process as a system where the five phases of the theory intervene: curricular, cognitive, didactic, epistemological and educational.

Research Development

1. Determination of Indicators

The authors who are mentioned in this section also belong in the section of theoretical foundation, it is just that in order not to duplicate the information they have only been located in the present section. It is through them that the indicators for the development of the concept of proportion are identified, as well as the indicators for the development of qualitative proportional thinking. It is worth mentioning that the identified indicators have been highlighted in bold type.

As an antecedent of what has just been mentioned stands the research by Ruiz (2002) who designed and applied a teaching proposal dealing with the concept of proportion and who found out different difficulties presented by students in the last year of elementary education, among them we find the two following: 1. Qualitative thinking of elementary school students revolving around proportionality is barely developed. 2. Students showed confusion when establishing proportions in an intuitive way and explicitly in geometric figures, since they were not able to establish proportions when they compare it in figures of similar length with the width of another.

Piaget (1978) argues that between 11 and 12 years of age, it is possible to observe in the subject the presence of the notion of proportion in different fields, such as: spatial proportions (similar figures), the relationships between weights and lengths of the arms of the scales, the probabilities, etc. Piaget also mentions that through his experiments he points out that the child acquires the qualitative identity before quantitative conservation and makes a distinction between qualitative comparisons and the true quantification. In fact, for Piaget (1978) the notion of proportion always starts in a qualitative and logical way, before being quantitatively structured. He stresses that I order for the student to develop his *qualitative proportional thinking* it is necessary to start from the notions of ***enlargement and reduction (1)***, following the idea of a photocopy or a scale drawing, assuming that the student at a really early age manages to recognize what is proportional using perception and observation. One way to express his *qualitative thinking* is to use linguistic expressions such as “greater than…” and “lesser than…”, that is to say, ***using verbal categories (2)***

In accordance with Piaget and Inhelder (1978), after the student develops the perceptual part (qualitative proportional thinking) an ordering when making comparisons appears (which is located in the *shift from qualitative proportional thinking to quantitative proportional thinking*), this can be verified when the student compares figures superimposing them taking as origin the indicator ***to compare (3)***. In this respect, Piaget points out that in this *shift from the qualitative to the quantitative* the student can build a figure enlarging it or reducing it, thus constituting the indicators ***to enlarge and to reduce (5)***. Later on, the student uses the measurement when making comparisons, firstly confronting parts of the object and superimposing one figure over another and then using a measuring instrument, conventional or not. Thus, ***measuring with instruments (6)*** represents another indicator, allowing the development of his *quantitative proportional thinking.*

It is important that the student when developing his *qualitative proportional thinking* manages to ***use the rule of three (7)*** assigning sense to this and not merely in a mechanical way (Ruiz, 2000), with which one more indicator is defined.

In terms of Freudenthal (1983), in order to establish proportions, *both intuitively* (that is, qualitatively) *and explicitly* (that is, quantitatively), the comparisons are expressed in two modalities: direct and indirect. The direct modality of comparing is when and object is ***superimposed*** over another object, which defines the indicator ***to compare directly (8)***, whereas the indirect one is when there are two objects and an ***instrument*** to compare them, like the use of a ruler or simply by counting obtaining as a result the indicator ***compare indirectly (9).*** The child is able to compare two objects indirectly and is able to do it in a qualitative and/or quantitative way.

It is important to mention that authors such as Piaget (1978) and Streefland (1991) mention in a natural way qualitative proportional thinking is first developed, through the perception of the empirical. On the other hand, it has been demonstrated that in the educational practice the use of algorithm is given priority, thus students developing a quantitative proportional thinking in a mechanic way, when in many occasions they have not developed qualitative proportional thinking. Thus, the qualitative-quantitative sequence is not always present in students.

Freudenthal (1983) points out that the comprehension, in an intuitive way, (i.e. qualitative), of proportion can be guided and delved in by the use of visualization and the latter can be illustrated using detailed constructions, where the drawings are differentiated and show what points correspond among themselves in the original and in the image. Freudenthal also suggests that upon working on the proportion of lengths flat figures are used as means of representation, for its expressiveness is more global, in the sense that they make it easier for the student the qualitative and quantitative comprehension between magnitudes by means of visual perception. From this perspective of mathematics, it is also important that the student manages to express *proportion* ***as a fraction (10)*** which constitutes one more indicator. Moreover, for Freudenthal (1983), it is precise that in teaching it is precise to take into account both ***internal proportions (11)*** and ***external proportions (12)***, defining the former as the relationships which are established between different values of the same magnitude, and the latter as relationships between values of different magnitudes; both proportions express two indicators to be taken into account.

Resorting to what has been mentioned by researchers in the previous paragraphs, a table in which the indicators referred to proportion as well as to qualitative proportional thinking is shown next; the didactic actions associated to such indicators are established as well.

Objects of study	**Objectives**	**Indicators**	**Didactic actions**
The mathematical concept of proportion	To establish proportions in a qualitative way	Compares directly (8) Compares indirectly(9)	♦ To superimpose figures ♦ To use a measuring instrument
	To establish proportions in quantitative way	Compares indirectly (9) Uses internal and external proportions (11, 12) Expresses proportion as a fraction (10)	♦ To use a measuring instrument ♦ To use a table relating data and writing the proportion as a fractions
The development of qualitative proportional thinking	To contribute to the development of qualitative proportional thinking	Enlarges and reduces (1) Uses verbal categories such as “greater tan” or “lesser tan” (2)	♦ To select reduced figures or enlarged ones by means of ♦ To use linguistic expressions
	To contribute to the shift from qualitative proportional thinking to quantitative.	Compares (3) Counts (4) Enlarges and reduces figures (5)	♦ To superimpose figures ♦ To count the sides of squares in one grid ♦ To draw enlarged or reduced figures in a grid

Table 1. Indicators and their didactic actions.

It can be observed in table 1 the diverse didactic actions which students should work upon, and which they can carry out in the interactive computational program. These didactic actions are expressed in a generic way like: To superimpose figures, To use verbal categories* To use measuring instruments, To use tables*, To select figures, To draw figures in a grid, To count the squares in a grid.

The actions marked with an asterisk, require of a recorder, which is external to the interactive computational program. When the student carries out these didactic actions it is necessary to use the recorder to have evidence. The verbal categories are recorded in the audio, as well as the comments by the students. The didactic actions “to use tables”, allows the student to relate date from the same column, between two columns or that the table can be filled out by him. For the case of relating data, the audio allows to identify this indicator.

The link between didactic actions and computational actions. The computational program was developed in order for the student to be able to carry out the didactic actions. For this research the computational program which has been developed allows to incorporate actions such as to drag figures, to access the figures of a box, to use a virtual pencil as though it were real, to make use of a grid to count the squares or to draw upon it, to make measurements with instruments such as a virtual ruler, to use tables to be filled out; al the actions afore mentioned are named ***computational actions.***

In table 2 the link between didactic actions and computational actions, necessary for the constructions of the concept of proportion, as well as the concept of qualitative proportional thinking is established. That is, computational actions are the ones which allow that didactic actions associated with each indicator of the construction of the objects of study can be carried out.

Didactic actions	Computational actions
To superimpose figures	To drag figures
To use measuring instruments	To use a virtual ruler
To use tables	To fill out a table
To select figures	To access figures
To draw figures in a grid	To use a virtual pencil
To count the squares in a grid	To use a grid

Table 2. Link between didactic actions and computational actions.

2. Design of Didactic Activities and Insertion in the Interactive Computational Program

In this section are first described the pedagogical elements from the interactive computational program which was overtly designed for this project. Later one the didactic activity is shown, specifying its purpose, which in founded upon the theoretical elements previously shown; the contextualized event which identifies it, in accordance with the theory of Mathematics within the Context of Sciences; the didactic actions which can be used by the student when dealing with the activity and, the computational action associated with this event; to finish with the insertion in the interactive computational program.

We present next the pedagogical elements from the interactive computational program. The pedagogical elements form the computational program allow the representation and visualization of instructions, the activities to be carried out, the help and options which the user can resort to, etc., in general the elements which are used in the learning process.

1(a) Familiar context 1(b) Motivation 1(c) Follow up

Figure 1. Screens from the interactive computational program

In accordance with Mathematics within the Context of Sciences, a familiar environment as well as metaphors of the real world adapted to sixth grade elementary students are presented, see figure 1a. The program is user friendly as it allows the user to log out, log in and send. For instance, you hold a click on the door to log out, see same figure 1a. A visual style is presented by means of font types, buttons and general aspects focused on elementary school children. Brevity in the texts is used, incorporating sounds and graphics to substitute possible content in the text. The type, style and size on fonts are legible. Messages are simple and concise, so as to avoid the user being confused.

The user is given tolerance of three attempts to correctly solve the activities and when he carries out an activity correctly, he is warned as a motivating means, see figure 1b. In the interactive computational program the student can look up his advance, see figure 1c.

When the student does not accomplish to carry out the activity correctly, then, animations are used to illustrate the concepts by means of examples and thus the association between concepts is immediately generated. Next we present the activity and its insertion in the interactive computational program.

Purpose of the Activity

The activity pursuits the construction of the concept of proportion and in consequence the development of qualitative proportional thinking. We start from what has been pointed out by Piaget (1978), Streefland (1991) and XXX (2002), on the fact that early teaching of proportion should start from qualitative levels of recognition of them, for this reason, the activity does not require of the use of quantities for its solution.

Contextualized event of the Activity

“Ricardo is ten years old, he went to Veracruz and at the harbor he saw a ship which liked him very much, the child drew it in a sheet of pager. When he came back to school he showed it to his teacher. She asked for four versions of the ship at the photocopier, some of them enlarged and others reduced, in different sizes. After that she took the photocopies to her students and asked them to choose the figure of the ship which was enlarged twice the size. Help them to find the ship which is enlarged”.

Didactic and Computational Actions of the Activity

In order to solve this activity the student can make use of the following didactic action: *to select the reduced figure* or the enlarged one to the given one. This corresponds to indicator (1): *to enlarge and reduce*, from the development of qualitative proportional thinking and is associated with the computational action of *accessing figures*.

The student can also make use of the didactic action of *superimposing figures*, this didactic action corresponds to indicator (8) of *directly comparing* when we aim at establishing proportions in a qualitative way (intuitive), similarly, it corresponds to indicator (3) of *comparing* the development of the shift from qualitative proportional thinking to the quantitative one.

In order to superimpose the figures, the student has the option to drag, with the mouse, whichever of the four figures to superimpose them over the original one and revise, by the use of visualization, whether the figures is enlarged or reduced in all the sides in the same quantity, the computational action involved corresponds to *drag figures*.

The recorder is turned on all the time in order to have the comments by students and their *linguistic expressions* which allow us to identify the qualitative proportional thinking through indicator (2) of *using verbal categories*.

If, not even in a second attempt is the student able to select the correct figure, it means that his qualitative proportional thinking is scarcely developed; however, as it has been mentioned, some students develop more of a kind of thinking than another, that is why they are given the option to move to didactic actions from quantitative proportional thinking. Then, there is the didactic action of *using a measuring instrument*, associated with indicator (9) of *comparing indirectly*, which corresponds to the construction of the concept of proportion both in a qualitative, and in a quantitative way, it will depend on whether the proportion is established in a numerical way (quantitative) or it is only verbalized (qualitative). At the same time, this didactic action is associated with indicator (6) of *measuring with instruments* from quantitative proportional thinking. The corresponding computational action is a *virtual ruler*, which allows the student to measure each side of the original figure, as well as each side of the figures that appear to select the one which is enlarged. It is worth mentioning that this interactive computational program randomly generates the figures (it is not always a ship), as well as their enlargement or reduction in different scales (which are not always expressed in whole numbers), with the purpose that it does not become a mechanic activity and that it is not memorized. In general the computational program randomly generates the data, the figures, the contexts and the tables.

Insertion of the Activity in the Interactive Computational Program

In a first screen the figure of the ship and 4 figures which are similar are shown, but with Little differences among them, see figure 1b. For instance, they can be twice the size, thrice the size, reduced to half or to one third of the original size and the child is asked to choose from the 4 figures the one which is enlarged to twice the size of the original.

When the child has selected one of the figures, it is because he has visualized the enlargement (1) or has dragged the figures in order to superimpose them and then be able to compare them directly (8) and define which one is enlarged twice the size. After selecting the figure, the computational program analyzes the choice made and following it sends an answer with the result of the analysis: a) If it is correct, another activity is shown to the child. B) If the selection is incorrect, the program sends a written message saying "the selection is not correct" and it asks if the child wants to have another attempt. If the child answers affirmatively, then, the same activity with the same data appears, but now with an auxiliary tool which is a virtual ruler, as it has been mentioned, which enables him to measure and make comparisons (indirect 9,6). If even with this support of the virtual ruler the selection is again incorrect, then, the interactive computational program presents another version of the same activity, which is randomly generated with other figures and other data, in order for the child to try again.

If after these attempts the student has not been able to select the correct figure, then, he is presented with one simulation of the activity, with other figures and other date, in such a way that the simulator superimposes figures and drags the virtual ruler, appearing the data of the measurements of the figures, in this way it can be by the actions performed by the simulator which figure is enlarged or reduced, in accordance with what is being asked. This allows the child to associate these actions with the ones he should have made in the attempts he carried out.

3. Implementation, Analysis and Discussion of Results

For the implementation we had a group of 29 students from sixth grade of elementary education in Mexico, specifically from a public school in Mexico City. The ages of the students ranged fluctuated between eleven and twelve years old. Six sessions were devoted for the work with students, each one lasting two hours.

The analysis and discussion of results are carried out in relation to the indicators of the construction of the concept of proportion (in a qualitative way) and to the ones of the development of qualitative proportional thinking.

Seven out of twenty-nine students are identified who chose the enlarged figure (Ind. 1), by means of visualization, though; it is worth mentioning that two of them managed to do that in the second attempt. However, in general it can be said that 24% of students, by means of visualization are able to identify the proportions and select the correct figures, that is, they have developed their qualitative proportional thinking. This can be observed through the recordings of the verbal categories (Ind.2) by students, such as "this is greater than the other", "it appears that this is twice the size", which were expressed, by six out of the seven students, during this activity.

The students who have not developed this qualitative proportional thinking are unable to visually identify the correct figure and they need to resort to direct comparisons and indirect ones. In the direct comparison they make use of the didactic action of superimposing figures, whereas in the indirect comparison, the didactic action is the use of a measuring instrument.

During the activity, eight out of twenty nine students drag figures thus fulfilling the indicator of comparing directly (Ind.8), which provides evidence that they can establish proportions in a qualitative way. Note that the action of superimposing figures also determines the indicator of comparing (Ind.3), which favors the shift from qualitative proportional thinking to the quantitative one. Thus, 28% of the students start to develop their qualitative proportional thinking and shifting to quantitative proportional thinking. Moreover, comments by three out of the eight students are recorded, such as: "this side is twice the size of the other" or "this side fits twice in the other", denoting the use of internal proportions (Ind.11) see table 1, which provides evidence of an incipient use of proportions in a quantitative way.
The remaining fourteen out of twenty-nine students used the two attempts which are given by the system to make a selection by means of visualization or the dragging of figures, without success. Moreover, in the audio recordings they registered linguistic expressions that show their difficulty to make the selection such as "the tree figures which are greater resemble each other". It is possible to say that these students have not managed to develop their qualitative proportional thinking.

Upon not being successful, the interactive computational program provides them with a virtual ruler. Only six out of the fourteen students measured (Ind. 6) the sides of the figures and compared them using this instrument identifying the correct figure, with which the indicator of comparing indirectly (Ind.9) is verified. Upon being measuring, the students obtain numerical values which compare sides to corresponding sides, establishing internal proportions (Ind. 11); which gives rise to establish ratios in an explicit way; six out of the fourteen students when carrying out this actions show signs of the development of their quantitative proportional thinking.

The remaining eight students out of the fourteen who used the virtual ruler, only measured one of the sides and selected the figures which had twice the size of the homologous side, but they did not notice that they had to measure all the sides of the figure to compare them to the figure they selected. These errors led them to the unsuccessful selection of the correct figure, which shows us that these eight students have not developed their qualitative proportional thinking either.

Conclusions

The different computational actions, dragging with the mouse, and using a virtual ruler, have a bearing on the didactic actions of superimposing one figure over the other to make the comparison or using a measuring instrument. All that depended on the kind of proportional thinking which students had previously developed either the qualitative or the quantitative one.

SEEING COMPLEXITY IN THE PROCESS OF CHILDREN'S BLOCK PLAY

Amy Noelle Parks
University of Georgia
amyparks@uga.edu

Diana Chang
University of Georgia
dchockey21@gmail.com

Nearly a century of research has established a relationship between the complexity of children's block play and mathematical thinking and reasoning in other contexts and in later years. However, most of this research has evaluated complexity by examining children's completed structures. This video-ethnographic study looks at mathematical thinking and reasoning during *block play as a way of contributing to learning trajectory research in early childhood mathematics that values diverse ways of thinking. The paper highlights opportunities for mathematical reasoning that emerged during the construction of "less" complex structures.*

The importance of children's block play for developing spatial thinking and geometric reasoning has been established through multiple studies (e.g., Casey et al, 2008; Guanella, 1934) These studies, dating back almost a century, have looked at ways to increase the complexity of children's block structures as well as ways that this complexity can support more complicated mathematical thinking, particularly in reference to spatial visualization skills, such as imagining flips and rotations (e.g., NRC, 2009). In addition, this body of work has documented relationships between block play and mathematical thinking more broadly (e.g., Caldera et at, 1999; van Nes & van Eerde, 2010). For example, recently Wolfgang, Stannard and Jones (2003) demonstrated a relationship between complex block play at age 4 and mathematics achievement in the 7th grade.

One emerging line of research, developed in response to increased interest in young children's mathematical learning trajectories (NRC, 2009), is the role that teachers can play in scaffolding children's spatial and geometric learning through block play (Clements & Samara, 2007; Kersh, Casey & Young, 2008; NRC, 2009). Gregory, Kim and Whiren (2003) demonstrated that trained educators could support students in creating more complicated block structures by talking with children as they played with blocks. Their study, like most others, evaluated the complexity of the block building through the examination of the qualities of children's completed structures.

The purpose of the current study is to add to this emerging line of research on children's learning trajectories in block play by evaluating children's thinking and reasoning as they go about the process of building with blocks. In doing this work, we hope to contribute to diverse ways of evaluting and scaffolding children's mathematical thinking during block play. Nearly all previous researchers have based their analysis of complexity on the completed block structures. For example, in 1934 Guanella described block structures as ranging in complexity from "pre-organized," where no structure is built, to piles and rows, to solid forms that include closed spaces, to three-dimensional structures (Guanella as cited in Casey et al, 2008). In their recent study, Gregory, Kim and Whiren (2003) expanded on the categories for analysis developed by several previous blocks researchers to evaluate student structures based on three broad categories: the complexity of the building, the complexity of arches, and number of dimensions (use of points, lines and planes) in the finished structures.

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

We would like to consider the possibility that complex mathematical thinking might not be entirely represented by increased complexity of completed block structures. In other words, a child might set a task for herself in work with blocks on a single plane that is more mathematically complex than one involved in creating a structure on multiple planes. We believe that the documentation of children's learning paths in their work with blocks ought to include an examination of the various cognitive demands and opportunities made throughout the building process as well as documentation of progression in creating more and more complex structures.

Guiding our study were the following research questions:

- What kinds of mathematical thinking and reasoning emerge during children's play with various kinds of blocks in both formal and informal contexts?
- How do interactions with others shape the mathematical thinking and reasoning that occurs?

Theoretical Framework

This study draws on Vygtoskian (1978) traditions that see play as central to children's development and see learning as an outcome of engagement in social activity. In his work, Vygotsky emphasized the tools that children draw on in their learning. These tools include the physical – such as Lego or wooden blocks – and also the social – such as ways of thinking or playing that are learned from other humans in social settings. Although Vygotsky's work around scaffolding is most often taken up to analyze interactions between children and adults, in this study we would like to acknowledge the role that children can play as the knowledgeable others in their peers' play. Particularly, during free time where some children may spend far more time than others with certain materials and thus develop expertise, children themselves may be able to scaffold the block play of their peers toward more complexity. Vygotsky also described the role that a cultural tool like "self-talk" can play in scaffolding a difficult task. He describes a child standing on a chair to reach a cookie, vocalizing each step in the process as a way of managing the difficult task. In a similar way, many children talk to themselves as they play with blocks. Following Vygotsky, we believe it is important to capture and analyze this talk as a way of gaining further access to children's mathematical thinking and reasoning.

Methods

This project is embedded in a larger ethnographic study of children in a rural community as they move from kindergarten to first grade, which seeks to explore their mathematical learning during this time span. As a small, rural school, Taylor County Public School is an ideal site for a longitudinal study because there is only one classroom for each grade. Nearly all of the students who attend the school are eligible for free lunch and about 90 percent are African American. These characteristics make this an important site for broadening the research base on learning trajectories around block-building because much of the reseach on blocks has occurred in settings where a majority of the children are European American and come from middle-income families. Data collection for the larger project includes weekly classroom observations supported by video- and audio-taping, individual video-taped assessment interviews with each child, audio-recorded parent interviews and focus groups, and video- and audio-taped observations of Parent Math Nights. Data collection and analysis for this paper has been informed by the multi-year relationship the first author has with the school.

As an ethnographic study, the research team seeks to understand children's experiences through both observation and participation. For this aspect of the project, this means that rather than comparing students' play and their block structures to pre-existing criteria, we attempted to document the mathematical interactions students engaged in during the process of play. In the preschool classroom, we took fieldnotes, audio-recorded conversations, and documented interactions with video cameras during both formal mathematics lessons and free-choice time, when children were allowed to choose among the many materials in the room, including Lego blocks, wooden blocks, and unfix cubes.

Data analysis was supported by the qualtiative data analysis program NVivo9. Using this program, the research team was able to code excerpts of field notes as well as segments of video clips for analysis. For example, a 30-second video segment could be identified and coded separately from a longer video clip. The observer who recorded the video also used the Nvivo9 program to describe the action going on in the video and transcribe some speech. Initially, data were coded based on the setting, the type of interaction, the materials used, and the mathematical concepts. The current codes are listed in the text box to the right; however, coding, particularly around describing the block play and mathematics, is being continually refined. At the time of writing this proposal, we still have another three months of scheduled observations in the prekindergarten. As a result, the analysis reported in the following section is tentative and still evolving. Over time, we hope to create a map of the opportunities for thinking and reasoning possible in the midst of block play.

Results

In this section, we describe several representative episodes of block play captured by videotape or fieldnotes over the course of the study. These episodes were chosen to demonstrate the mathematical thinking and reasoning that occurred as children interacted with different kinds of blocks, in different settings, and with different people. While all are unique, the kinds of thinking and interactions that occurred in each episode can be found across our data record.

Episode 1: Carter and Wooden Blocks

One afternoon, Carter, who frequently played with all kinds of blocks during free choice time, chose to build with wooden blocks. The block set available in the classroom was relatively traditional, with a variety of rectangular and triangular prisms, cylinders, and arches. On this occasion, Carter decided to build a road out of blocks, announcing his intention to no one in particular. Carter began by laying down a 6-by-3-inch block. He then put together four 3-by-1.5-inch blocks, choosing from dozens of blocks spilling from the tub around him. For the next road segment, he chose two 6-by-1.5-inch blocks, putting them side by side. He then used another 6-by-1.5-inch block and then two 3-by-1.5-inch pieces. Finally, he chose two 3-by-3-inch blocks for the last segment in the road.

The wooden blocks, which were designed to make many equivalent shapes possible, allowed Carter to experiment and practice with composing and decomposing shapes. Carter seemed to embrace this activity as part of his play. After all, several of the large 6-by-3-inch blocks were available and Carter could have chosen to create a road out of identical blocks. Instead, he seemed to go out of his way to make as many equivalent combinations as possible in the building of his road. This ability to compose and decompose shapes has been highlighted as an important mathematical concept for young children because children "who can compose shapes develop better understanding of composing and decomposing numbers" (NCTM, 2010, p. 56) as well as a foundation for geometric concepts. In addition, play like this afforded Carter the opportunity to practice visualization because he needed to orient blocks in the proper direction to make equivalent shapes and to choose the desired block from a pile in the tub.

It is also important to note Carter's intention to build a "road." Traditional rubrics for scoring the complexity of block structures would categorize the road as less complex than other structures because of the lack of vertical building, arches and enclosures. However, this analysis does not take into account Carter's intentional construction of an object that he likely visualized in his head before he created it as well as his efforts to create equivalent segments. In considering complexity, it is important to consider not just the finished product (in this case, a straight line), but also the particular tools used to construct the line (blocks of various sizes and shapes rather than all identical blocks and equivalent block units rather than varyingly-sized units). In this episode, Carter played by himself with little scaffolding from others; however, the available tools contributed to his mathematical thinking. This includes both the opportunities for visualization, identification, composing, and decomposing provided by the blocks, but also the story scaffolding provided by other toys. Casey and colleagues (2008) found that telling stories contributed to children building more complex block structures, and in many ways available toys served this purpose for children in the classroom. For example, in this case, it is unlikely that Carter would have chosen to build a road if cars and trucks had not been available to drive on it.

Episode 2: Markus and Unifix Cubes

One morning toward the end of free-choice time, Markus came upon a bucket of unifix cubes scattered across the carpet. Initially, he bent and began to stack as many as he could into a tower nearly as tall as himself. After holding his tall tower against himself, he sat and began breaking the tower into smaller chunks. He then picked up one of these smaller towers and counted each cube, touching it as he said the number. After counting seven cubes, he reached out grabbed a loose cube and added it on. He then repeated the process, making four other towers of eight cubes each. He then laid these towers against each other on the floor. When he made his fifth tower, he laid it down by the others to check its length and then took off two blocks when he realized it was too tall. At this point, Dahlia and Trevor approached and began to stack the blocks into tall towers. Markus corrected them, saying "We need to make eight! For Bingo." Trevor and Dahila accepted this and began to make towers of eight blocks, each of them counting the blocks in their finished towers one at a time, touching each block and laying their completed towers down next to the pile Markus had made. Other children started to approach, making various lengths with the cubes. Markus reiterated that the towers had to be eight long. At this time the teacher approached and asked Markus, "How many are in your tower?" He picked one up and counted for her, touching each block, "1,2,3,4,5,6,7,8." She replied, "Very good."

Unifix cubes are not often considered in block research; however, as we watched children play with them during the informal moments in the classroom, it seemed odd to exclude them. Because these cubes could only be used as isolated ones or as towers, the mathematical thinking they were most likely to elicit involved counting and comparison. Students compared towers to each other (as Markus did when he was making units of eight), compared them to themselves (as Markus did when he made his first tall tower), and compared them to objects in the room. Students also often counted these blocks, practicing one-to-one correspondence as they did so. Sometimes, this counting seemed to serve a particular purpose, as it did for Markus, who knew that the blocks were passed out in groups of eight for Bingo because the boards had eight spaces. However, more often students seemed to count simply because they had the blocks. This may have been because the teacher frequently used these blocks for counting in formal lessons and also tended to ask children to count the blocks whenever she saw them being used during free-choice time. The unifix cubes seemed to offer fewer opportunities for spatial reasoning than other blocks, although opporutnities to compare lengths did encourage students to talk about more, less, longer and shorter, and to make adjustments to their towers as a result of these analyses. Markus's use of his already constructed towers of eight to measure his new towers demonstrated an ability to reason about length and quantity as he was able to recognize that towers of the same length would have the same amount of cubes without having to count again and was also able to adjust towers by taking off or adding on cubes to get the correct lengths. The task Markus set for himself and the way he set about it reveal aspects of his thinking and reasoning that would not be apparent in the completed pile of towers of eight blocks.

In this episode, the blocks themselves and the potential of a Bingo game later provided scaffolding for Markus to explore length and comparison and to practice counting. Markus, himself, provided this scaffolding for other students, by repeatedly naming the task at hand. Although the other students did not talk about the Bingo game, it is likely that this real-world purpose, served to persuade them to engage in the counting activity Markus set up. On the other hand, the teacher's intervention in this case did little to scaffold mathematical thinking. Markus had already counted the blocks in multiple towers by the time the teacher asked him to count. Indeed, he already knew there were eight blocks in the tower he was holding when she asked him to count the blocks. He performed the task anyway and her response did little to either acknowledge the thinking he had already done or to push him toward new mathematical engagements.

Episode 3: Xavier, Carter and Legos

At the beginning of free-choice time, Carter pulled out the Dulpo Lego blocks. He placed a large blue mat (25 by 25 nodes) on the floor and began to attach blocks along the perimeter of two sides. Nearby, Xavier began to build a tower of 2-by-4 blocks. Once the tower was 10 blocks tall, Xavier attached it to the mat on which Carter was working. Carter rejected this effort, saying "No, I'm making something right here." He reached out and removed Xavier's tower. Xavier accepted this correction and moved away from Carter, who followed him asking, "You want to help me?" Xavier tried one more time to make a tower and attach it, but Carter again removed it from the board. He gestured to the blocks he had placed along the perimeter and said: "I'm doing this." Xavier began to join Carter in filling up the board with a single layer of blocks. This went smoothly until the entire board was nearly full. The boys then began to search for pieces that would exactly fit the few remaining holes. Carter dug through the box to find a 2-by-2 square, which he placed in a matching open space in the center of the board. Xavier turned a rectangular block to fit a remaining hole. The last space in board required a 2-by-8 block; however, one of the surrounding blocks had plastic googly eyes projecting from the side, which made it impossible to fit an appropriately sized block in the adjacent space. After both Carter and Xavier tried a number of correctly sized blocks with little success, they appealed to the researcher observing. She asked them to feel the side of the block with the raised eyes. Xavier did so and then took that block out, replaced it with an identically sized one, and then filled in the last hole before beaming up at the camera. In all, this process took Xavier and Carter 25 minutes.

The Dulpo Legos, with their defined working spaces on mats, primarily rectangular shapes, and ease of fitting together, scaffolded different kinds of mathematical thinking than wooden blocks or unifix cubes. Children were able to build much taller structures with the Dulpo Legos than with the wooden blocks. In addition, the concepts of area, perimeter, and rotations were frequently explored during Lego block play. As Carter did in this example, students frequently created a perimeter first and then filled it in. This required choosing blocks that would be exactly the same length as the mat and negotiating the tricky business of turning corners. Carter, who spent a lot of time in the block area, performed these tasks with certainty, rarely needing to remove a block and replace it with one that had a different length or width, while other children frequently needed to make such adjustments.

These differences in the ways children went about building similar structures reveal differences in development of visualization skills and understandings of length and width and would be unlikely to be captured in the evaluation of a final product. Similarly, in this case, many of the scoring systems for complexity would rank a structure as more complex if it had the tower that Xavier proposed adding; however, Carter's sustained commitment to filling the board demonstrated perseverence with a task and also created an opportunity for both him and Xavier to think about how to fit geometric pieces together exactly, which required anlysis of shapes, lengths and widths and work with rotations. Typically, when children added towers to constructions the play became focused on creating cities or sometimes parking garages, rather than on a task like filling all of the available space on the mat. Thus, Carter scaffolded a more mathematically complex task for Xavier through his commitment to working only in one layer. \

Episode 4: Dahlia, Her Mother & Legos

At the Parent Math Night, one of the stations consisted of several boxes of Legos, including special pieces, such as wheels and trees, and written directions for making specific projects. Dahlia came to the event with her mother and her six-year-old sister, Tamara. Her mother took the written directions for a house, held them in front of Tamara, and quietly talked her through the process of building. Dahlia looked on for a moment and then began to build a tower with 2-by-8 blocks. After watching Tamara for a moment, she searched through the box to find window and door pieces the same size as the blocks. She pulled on her mother's sleeve and said "See my house." Her mother looked over, saying, "That's pretty, Dahlia. What you going to do next?" Dahlia pressed her tower onto a Lego board and began to add blocks to her board. After a moment her mother smiled told her to look at Tamara's house, which had a roof, doors, and other accessories, as well as four walls creating the structure. Dahlia looked on for a moment and then began to add additional blocks to her construction.

In this episode, Dahlia, with her mother's help, used her older sister's construction as a model for her own work so that while Tamara constructed a house that mirrored the one pictured in the Lego directions, Dahlia turned her tower into a "house." In someways, viewing the tower as a house was merely cosmetic, such as in Dahlia's decision to add the clear bricks to stand in for windows. However, Dahlia's building of a tower was her independent translation of Tamara's four-walled enclosure. In her attempt to emulate her older sister, she needed to watch what Tamara was doing and decide how to replicate it with the blocks available to her, a process that encouraged the development of visualization skills and manipulation of geometric figures. Her mother encouraged her to add complexity to her structure by prompting her to think about what she should do next and presenting Tamara's house as a model. Unlike the teacher and parapro, both in the classroom and at the Math Night, the parents we observed rarely asked their children to count or to name shapes. Rather, parents scaffolded their children's work and thinking through engagement in the same or similar tasks. For example, the father and son at the table with Dahlia both made their own airplanes. This sort of scaffolding seemed to allow more opportunities for spatial thinking and reasoning to unfold than the teachers' efforts, which continually redirected children back toward traditional preschool mathematics, such as counting.

Discussion

Given the concerns expressed in many recent reports (e.g., NAEYC & NCTM, 2002; NRC, 2009) about the quality of mathematics experiences many young children receive, particularly poor and minority children, we believe it is important to consider ways that opportunities for complex thinking and problem solving can be incorporated into preschool and kindergarten school days in both formal and informal spaces. In the current climate of standardized testing, many early childhood teachers have become focused on basic skills, which has led to a reduction in free play. However new research has shown that these play opportunities are critical for complex mathematical thinking later (NRC, 2009).

This ethnographic analysis of block play raises a number of issues for mathematics educators to attend to as they develop early childhood mathematics curricula, engage in professional development with early childhood teachers, and do further research on young children's learning trajectories. First, it is important to recognize that the complexity of mathematical thinking young children engage in during block play may not be entirely captured in the finished structures. The research community would benefit from increased attention to creation processes, and children and teachers would benefit from increased opportunities to talk about their thinking during and after their work. Second, children's play with blocks needs to be scaffolded to maximize opportunities for mathematical thinking; however, this scaffolding does not always need to come from a teacher in either a formal or informal setting. Well-chosen materials can scaffold particular kinds of thinking, and other children and parents can also support children in problem solving. More research needs to be done on how to build on the strengths parents and children bring to this process. In addition, teachers need to learn both how to watch children during block play to figure out the mathematics that may be present and to recognize the more complex process skills that young children need to develop along with counting and shape recognition. Finally, we would be remiss not to note that in our study, as in much previous work (e.g., Kersh, Casey & Young, 2008), gender mattered in block play. Nearly all of our classroom clips with Legos, wooden blocks, and unifix cubes show the work of boys. However, during Parent Night and in the assessment interviews, girls engaged enthusiastically with the blocks, as Dahlia did in the described episode. Creating spaces where girls were expected to build with blocks and where they did not have to struggle to maintain access to the materials seemed important in giving girls access to these learning opportunities. Guided play as part of formal lessons in classrooms could potentially provide another welcoming space for girls to engage in block play.

Developing learning trajectories around blocks that include both images of what finished structures may look like and descriptions of processes that children go through as they engage with these materials is important to the study of children's early learning broadly and, more particularly, to the study of the relationship between formal and informal learning. Teachers will be able to use these trajectories to learn about the deeper mathematics embedded in block play and to make connections between formal and informal lessons. It is important to both theory and practice to develop these trajectories by looking at the thinking that goes on during block building in a variety of social settings not simply at a progression of completed structures. This theoretical view is likely to be more inclusive of diverse mathematics and of diverse children.

THE SOCIOCULTURAL CONTEXTS OF PRE-K CHILDREN'S MATHEMATICAL EXPERIENCES IN SCHOOL

Eun-Ae Son
University of Georgia
eunaes@uga.edu

This study is conducted to understand the sociocultural contexts of pre-k children's mathematical experiences in their school lives. Through interpretive ethnographic research, I observed pre-k children's natural mathematical experiences in the classroom focusing on the sociocultural contexts embedded in their mathematical learning. This study was drawn from Bruner's idea about the culture of education, and Bakhtin's ideas of language were employed in the analysis. This study discusses the influence of teachers' directed mathematics activities on children's informal experiences and cultural dynamics in mathematical experiences in pre-k classrooms. The implications of pre-k children's meaningful mathematical learning are provided.

Children's lives are always related to mathematics, and many mathematical attributes are derived from everyday life. Through their ordinary life experiences, children naturally engage in significant levels of mathematical activity (Trafton & Schulte, 1989; Clements, Sarama, & DiBiase, 2004). Considering children's early ordinary experiences not only as significant practices for present mathematical learning but also as a cornerstone for later mathematical learning, many mathematics education scholars have been paying more attention to informal mathematics. With a heightened awareness of values of informal mathematical experiences, a number of researchers of mathematics have explored children's mathematical experiences while considering the social and cultural contexts in which the children reside (Ginsburg and Russell, 1981; Stigler and Baranes, 1988; Nunes, Schliemann, & Carraher, 1993; Tudge and Doucet, 2004; Seo and Ginsburg, 2004). However, many studies have been primarily concentrated on the children's social and cultural backgrounds in generic ways. For example, in many of those studies, artificial factors, such as X, representing children's social backgrounds were used to compare or examine their influences on or their associations with children's mathematical learning. Graue and Walsh (1998) note, "researchers who look too widely risk losing the chance to look very carefully" (p. 10); a more careful analysis that pays attention to social and cultural contexts within children's mathematical experiences in school and the relationship between the local context and the larger context is necessary. The purpose of this study is to understand the sociocultural contexts of pre-k children's mathematical experiences in their school lives. Before zooming in on the main foci of this study, I first position the perspective of the sociocultural contexts adopted here by mainly referring to Bruner's idea about the culture of education. Second, I introduce Bakhtin's idea of language which was employed in the analysis of this study.

Theoretical Framework

The Sociocultural Context of Mathematical Experience

In his book, *Culture of Education* (1996), Bruner states that "school is a culture itself" (p. 98). He also presents the classroom as a "living context" (p. 44) where "teachers and pupils come together to effect that crucial but mysterious interchange that we so glibly call *education*" (p. 44). A school classroom itself is a sociocultural context in which mathematical knowledge and experiences are shared, negotiated, and constructed. Bruner (1996) considers the influences of the broader society on the school classroom as well as the impact of school culture on the individual child:

> [S]chool can never be considered as culturally "free standing." *What* it teaches, what modes of thought and what "speech registers" it actually cultivates in its pupils, cannot be isolated from where the school is situated in the lives and culture of its students. For a school's curriculum is not only about "subjects." (p. 28)

According to Bruner, the classroom is, rather than the physical setting as an instructional environment for young children, a living context which reflects implicit cultural values of the larger society where shared and negotiated ways of thinking and collective cultural activities are produced. Bruner (1996) adds that "education is never neutral, […] education is always political" (p. 25); therefore, social values reflected in school curricula and classroom culture cannot be free from moral-political considerations of social class, gender, race, and other prerogatives of social power. Bruner's view of the classroom as a culture itself is consistent with Stigler and Baranes' (1988) account of the cultural attributes of mathematics learning. They argue that mathematics by its very nature is cultural:

> The practice of mathematics is not seen as the discovery of truths existing outside of the realm of human activity; rather, it is considered to be as domain-specific, context-bound, and procedurally rooted as are other forms of knowledge. Mathematics learning is not uniquely immune to the influences of culture, but rather, it is as cultural as is learning in other domains. (p. 258)

I consider the sociocultural context of children's mathematical experiences not only as an important influential factor on their learning but also as a mirror reflecting cultural values about mathematics in our society.

Another concept discussed by Bruner is important to the purpose of this study: "mental life—and what we call 'intelligence'—is interactive, not just within the individual's head. Intelligence depends hugely on interaction, on understanding what others have in mind" (Bruner, 2008, p. 101). Graue and Walsh (1995) also note that "the context is the world as realized through interaction and the most immediate frame of reference for mutually engaged actors" (p. 9). Even though mathematics can be conceived as an entirely mental activity, it is socially constructed and shared through reciprocal interactions. In order to understand children's mathematical experiences in schools, it is necessary to consider the sociocultural contexts which the children create as well as reside in. That is, children's mathematical experiences need to be understood within their sociocultural contexts, which include individual and social meanings derived from their interactions and relationships with people and objects.

Bakhtin's Idea of Language

Heteroglossia vs. Unitary Language

Bakhtin's view on language provides valuable insights on social, cultural, and political phenomena of education. By contemplating the social nature of language, he shows the dynamics of world views and socio-ideological phenomena in which we are influenced by, and sometimes controlled by, the means of language. Introducing the concepts of *heteroglossia* and *unitary language*, Bakhtin (1981) explains that a living language is in tension-filled dynamics between *centripetal forces*, "verbal-ideological centralization and unification," and *centrifugal forces*, "decentralization and disunification," which "intersect in the utterance" (p. 272). Bakhtin's notion of *heteroglossia* can be referred to as a social diversity of speech types, individual voices, or different dialects, which is *centrifugal force* that opposes *centripetal force* of *unitary language*—socially, historically, and culturally constructed norms of language. Therefore, each utterance undergoes and participates in this process of centralization and decentralization and is stratified. In addition, to Bakhtin, language is not just a means of conversation, but a pathway of social and ideological dynamics. Even though he employs linguistic terms, he expands his ideas of language to sociology, affirming that language is "conceived as ideologically saturated, language as a world view, even as a concrete opinion" (Bakhtin, 1981, p. 271). Based on this concept of language, the nature of language is broadened to include "processes of indexical meaning that anchor utterances to their linguistic and nonlinguistic contexts and to unspoken background assumptions" (Shweder, et al., 2006, p. 742).

Dialogic Living Language vs. Monologic Dead Language

One of the Bakhtinian scholars, Volosinov (2000)—a Russian linguist and also Bakhtin's close friend, whose work largely coincides with Bakhtin's work—introduces the concept of *dialogic living language* as opposed to *monologic dead language.* According to Volosinov, *isolated, finished, monologic utterances* are "divorced from its verbal and actual context and standing open not to any possible sort of active response but to passive understanding" (p. 73). Volosinov (2002) considers *dialogic living language* as "the actual reality of language-speech" (p. 94) and argues that "language is a continuous generative process implemented in the social-verbal interaction of speakers" (p. 98). According to Volosinov (2000), a word is "the product of the reciprocal relationship between speaker and listener, addresser and addressee", and "the immediate social situation and the broader social milieu wholly determine" (p. 86) the structure of an utterance and the meaning of a word.

Bakhtin (1981) also places an emphasis on word's orientation "toward the listener and his answer" (p. 280). In living dialogue, any speakers, speech subjects, or addressers mutually reflect one another. Individual utterances are not "indifferent to one another, and are not self-sufficient" (Bakhtin, 1986, p. 91). Bakhtin (1986) elaborates this idea that "each utterance is filled with echoes and reverberations of other utterances to which it is related by the communality of the sphere of speech communication" (p. 91). Volosinov's emphasis on reciprocal relationship between addresser and addressee and immediate social situation of communication has a resemblance to Bakhtin's illustrations of a living word and dialogue. Consequently, *dialogic living language* can be resumed in the words of *continuously generative process implemented in reciprocally reflective social-verbal interactions*.

I appropriate Bakhtin's idea of the dynamic nature of language because his idea of language as social phenomenon provides the view on language as a culture and informs cultural dynamics in the school classroom. Based on these two conceptual contrasts regarding language as discussed by Bakhtin, this study explores the sociocultural contexts of children's mathematical experiences in the pre-k classroom. Research questions are as follows:

1. What mathematical practices and concepts do pre-k children experience in school life?
2. How are the mathematical practices and concepts that pre-k children experience in the classroom related to the sociocultural contexts of their experiences?
3. What are the educational meanings which the children's mathematical experiences imply?

Methods

I appropriate interpretive ethnographic research, and research site and participants are as follows:

Site	Participants
- A rural area public school located in central Georgia - Total population of county: 1,863 (U.S. Census Bureau, July,2008) - High poverty rate (Nearly all students, free lunch) - A single public school in a county which serves PK-12 grades with fewer than 300 students	- One pre-k classroom, 2 teachers - Pilot study (2009-2010): 20 children - New school year (2010-2011): 18 children (mostly African American children, 2 White girls, 1 Mexican American ESL learner)

Multiple data were collected though the method of participant observation. As part of a larger study, I observed the pre-k classroom for 6 sessions from February 1 to April 19, 2010, for a pilot study and for 8 sessions from September 9, 2010, to February 10, 2011. For the pilot study, I observed calendar time, breakfast time, whole group lessons, and free play time in order to get familiar with the research site and recognize various situations in which mathematical practices occurred. After the pilot study, I observed this pre-k classroom with newly enrolled children for 8 more sessions while focusing more on large group activities, small group activities, and children's free play. The collected data include jotting notes, expanded field-notes, voice records, and video records. While recording videos and audios, I took jottings and tried to record all my momentary thoughts, initial impressions, or additional information about the situations. After each observation, I wrote the expanded field-notes. Data analysis was an inductive process. Reading through the large amounts of collected data, I made preliminary notes of what seemed relevant. Then, I repeatedly investigated the collected data and made more focused coding. These were mostly based on the research questions and classified under the specific themes of children's social contexts in mathematical experiences focusing on the relationship between their learning and cultural experiences.

Results: Pre-K children's Mathematical Experiences in Context

Adult Directed Mathematical Experiences

Even though the pre- k teacher's roles were different depending on the class time schedule in each day, the teacher played a director's role by introducing materials and activities, asking questions, and reading books to the children during large group circle time, small group activity time, and free play time. Regardless of the different forms of activities, the teacher-children interactions were limited to the typical form of closed question-answer type.

> The teacher starts reading the title of the book, *Run, Bunny, Run*. After reading the first page, she points at the number on the shirt that the character Bunny wears and asks a question:
> Teacher: What number is Bunny? / Children: Three. / Teacher: Three. What number is bear?
> Children: Two. / Teacher: Two. What number is beaver? / Children: One.
> Teacher: One. What number is chicken? / Children: Four.
> Teacher: Who is in the lead? (She points at the first animal Bunny.) / Children: Bunny.
> Teacher: Bunny. Bunny, first. Can you … say, he is first. / Children: He is first.
> Teacher: Bunny is first. O.K.? Now, who's last? (She points at the last animal in the race.)
> Children: Bear. / Teacher: Bear. Bear is in the end; he is last. Bunny's first.
> - From observation field-notes, Nov. 14, 2010

The teacher's questions related to mathematics predominantly consisted of counting, reading the numbers, and matching the quantity of objects to the numbers: What is this number? How many dots? Can you count? What comes after ten? Can you find the number 8? During whole group time, the teacher's questions were directed to the whole group, and sometimes one of the children was called on and asked to answer the teacher's question. When the teacher asked questions to the whole group of children, only a few of them answered. The teacher always gave the children cues by gesturing to indicate that she wanted the children to stop counting or by making first sounds of the answers. Then, the children just stopped when the teacher said or showed stop cues. Therefore, many of the children counted the numbers without paying much attention to what they were saying. In small group, the children took turns one by one in a group. The children were required to accomplish mathematical tasks individually in a group activity. Compared to large group activities, in a small group activity, the children were more restricted because the teachers could manage their behaviors more efficiently with a small number of children. Teacher's questions were almost same with those in whole group activities. During free play time, the teacher intentionally asked the children to count objects they had in that moment when she found any situations related to counting, or sometimes without any consideration of children's play contexts. Her intentional questions sometimes promoted the children to practice counting and recognize how many objects they had. Nevertheless, when the teacher's question was out of context, these questions cut off the children's play and did not stimulate the children's meaningful counting. Likewise, the teacher's interaction with the children primarily centered on her main goals of subject area such as counting and naming numbers when it comes to mathematics.

Mathematically Interactive Experiences among Peers

During the large group activities or the small group activities, the children's interactions were limited and sometimes rather restricted. Mostly, they took turns to accomplish same mathematical tasks. They were required to quietly see what other children did and to answer the questions that the teacher asked to all the members in a group. In free play time, relatively more peer interactions related to mathematics were observed, particularly in the block area. When the children played with Lego blocks, they shared the shapes of Lego pieces and explored the form and the shapes of blocks. Even when they did not verbally interact with their peers by using mathematical language, there were mathematical interactions among children, in which they shared geometric information and their thoughts about others' mathematical works. The most common pattern of "playing numbers" is that they reported to peers how many objects they had, for instance, shouting "Look! I(we) got two!":

> Joseph and Ted are playing with the magnetic numbers. They are putting them on the wall of the teacher's desk. With the magnetic numbers, they create some images on the wall. Ted picks up the number four and puts it on the wall. He says, "I got a four! You want me four!" (Do you want my '4'?") He puts it by the number four previously placed on the wall. He makes these two "four" closer and says, "We got two fours." - From observation field-notes, Nov. 18, 2010

"I got (number)!" game encouraged children to count the number of objects or name the numbers. Playing with other peers, the children not only shared mathematical concepts but also promoted each other to engage in mathematical play. However, their interactions were still limited in a variety of mathematical concepts. Usually, verbal interactions among children that contain mathematical concepts were concentrated on the matter of how-many. There was no interaction related to measuring, comparing size or quantity, or sorting. Moreover, such mathematical interactions were observed only occasionally.

Silent, BUT Engaged Learning Experiences

Through building blocks and Lego, playing with puzzles and toys, drawing, and making artwork, the children naturally engaged in mathematical practices. They counted a quantity of materials, measured amount and space, identified numbers and shapes, compared size or quantity, and sorted objects based on the characteristics such as colors, shapes, and uses. When they played alone, the children sometimes paid longer and higher attention to their play and spontaneously repeated mathematical practices. For example, Dayton, who was very good at counting and naming numbers during the formal mathematics lesson, played with a clock puzzle. He repeated counting and reading numbers, putting puzzle together, and building tower with puzzle pieces and continued his play longer than 30 minutes:

> Dayton is playing with a clock puzzle. (…) After finishing the puzzle, he takes out all the puzzle pieces one by one in an order. He makes a tower with the pieces from the number one to seven in order. From the number eight, he makes another tower beside of the first one. Now, he has two puzzle piece towers: one 5-story tower and one 7-story tower. When he was about to move the piece on the top of the 7-story tower, this tower fell down. He gathers the fallen puzzle pieces. With seven gathered pieces, he makes one 3-story and one 4-story tower. He takes all three puzzle pieces from the 3-story tower. Grabbing these puzzle piece with his right hand, he moves the pieces of the 4-story tower one by one to the side of 5-story tower. Finally, he has three puzzle pieces in his right hand, a 4-story and a 5-story tower. He puts one more piece on the 4-story tower and makes two same-story towers. He carefully puts the last two pieces on each of the towers. He shouts, "Look! Look! I made towers!" - Observation field-notes, Nov. 14, 2010

While managing the height of the towers in order to make same stories of two twin towers and building towers in this way and that, Dayton did mathematical work such as comparing heights, dividing numbers, and making in order and generated his own mathematical meanings from that task. Playing with this puzzle, even though this child worked very silently and independently without verbal and social interactions with others, he was more deeply engaged in his mathematical work than any other experiential contexts. He used and experienced a variety of mathematical concepts, spontaneously repeated these mathematical practices, and generated mathematical meanings in play.

Discussion: Educational Meanings in Children's Mathematical Experiences

First of all, this study found that children's mathematical experiences were more limited when the teachers directed the mathematical lessons or the children's free play than when the children played alone or with peers. During free play, their experiences with and explorations of mathematical factors were relatively more diverse. They used informal mathematical knowledge, such as sorting, ordering, measuring quantity or sizes, and comparing, and practiced these mathematical concepts spontaneously. Meanwhile, the teachers' concentration on the children's numerical abilities had an influence on the children's use and employment of their mathematical knowledge and skills in their free play. Teachers' mathematical interactions helped the children frequently recognized the numbers and were autonomously engaged in counting the numbers of objects during free play. However, even though the invisible interactions among the children included some mathematical concepts other than numeracy, their verbal interactions mostly referred to naming numbers and counting.

Mathematics in this pre-k classroom reflects the tension-filled cultural dynamics between predominant, centralized, and *unitary* values and decentralized, disunified, and *heteroglot* values, which are discussed by Bakhtin. Children's *heteroglot* informal mathematical experiences appeared during free play time. However, unitary mainstream school mathematics centralizes children's *heteroglot* mathematical experiences and informal mathematical knowledge and values, closing the diversity of mathematics by practicing them mainstream *unitary* rote methods. Current schools' and teachers' inclinations to conventional school curriculum reflect Bakhtin's (1981) discussion of *unitary language* as a utopian philosopheme. Schools have concentrated on utopian *unitary* knowledge, which "makes its presence felt as a force for overcoming this heteroglossia" (Bakhtin, p. 270) and have ignored their own *heteroglot* nature. In school, pre-tailored and pre-established conventional school knowledge is generally transmitted to students as a universal and singular language by teachers without inner meditations. While emphasizing *unitary* mathematics curriculum, schools might neglect or devalue other potentials of children's informal math experiences. Bakhtin (1981) explains underlying political aspects of language by stating that "[a]s a result of the work done by all these stratifying forces in language, these are no 'neutral' words and forms" (p. 293). Likewise, the tension-filled cultural dynamics between *unitary* and *heteroglot* cultural values in mathematics can all be associated to social and political stratification of powers, distinctions, and rewards.

This finding puts more emphasis on the importance of adults' roles in amplifying children's informal mathematical knowledge and experiences. Wheatley (2003) indicates that teachers do not make use of children's informal mathematical knowledge and skills for their meaningful learning experiences. According to Wheatley, teachers have either too little content knowledge to recognize mathematical concepts, which are embedded in children's ordinary lives, or are unable to naturally expand these children's informal mathematical knowledge to their learning. Clement, Sarama, & DiBiase (2004) also point out that pre-k children bring their informal mathematical knowledge to school and that teachers should help them to "mathematize" their pre-experienced knowledge. Gutstein, Lipman, Hernandez, & Reyes (1997) argues that "helping teachers build on children's informal knowledge in mathematics classrooms helps children use their intellect well, make meaning out of mathematical situations, learn mathematics with understanding, and connect their informal knowledge to school mathematics (p. 711)".

Second, children's mathematical interactions with peers rarely occurred. In particular, during teacher's directed lessons, not only were children's peer interactions restricted, but also, the teachers' closed questions did not promote the children's discussions related to mathematical knowledge and expected them to work independently. During free play time, mathematically interactive conversations were not frequently observed among the children. This result reflects Hatano and Inagaki (1998) discussion of "American teachers' inclination toward individualism" (p. 90), which is opposed to Japanese teachers' sharing students' experiences and ideas. These authors explain that American teachers tended to believe "students benefit most from individualized lessons, [and the American teachers] tried to optimize their instructions by individualizing it" (p. 90). Rogoff (2003) also demonstrates this prototypical structure of dyadic interaction in American schools by affirming, "U.S. classrooms are commonly structured with the teacher taking a speaking turn between each child turn" (p. 148).

Moreover, teacher's guided repeated questions as "what is this number?" and "how many?" are deplete of contexts of classroom discourse. While tossing about the simple, rote, and monologic questions and answers, the teacher and the children give and take abstract words without any deeper contextual understanding and without openness to possible diverse responses. This classroom discourse's abstraction of the contents of number, without consideration of the placed temporal and spatial contexts, is comparable to Bakhtin's notion of *monologic dead language*. According to Volosinov (2000), *monologic dead language* is "already an abstraction"

(p. 72), and the abstract objectivism neglects "the dynamics of speech," "living multiplicity of meaning and accent," and "the inner generative process of language" (Volosinov, p. 77). Volosinov (2000) notes, "In reifying the system of language and in viewing living language as if it were dead and alien, abstract objectivism makes language something external to the stream of verbal communication" (p. 81). In this classroom, the contents of speeches are externalized from the stream of verbal communication while decontextualizing the contents and knowledge which each utterance infers. Therefore, someone else's hackneyed postulations are handed down from individual to individual, from people to people, from generation to generation, in the shape of formalized and systemized speech, which has depleted its histories and contexts. Therefore, through this *monologic dead language* of classroom discourses, to which children are routinely exposed, they are socialized to the school language uses and conceptual and ideological meanings of mathematical knowledge. Schools make children concentrate only on predominant school knowledge dehumanized, decontextualized, and abstracted and disregard the *heteroglot* nature of the world, their living world, without meditation.

Finally, I question, "What are meaningful mathematical experiences to pre-k children?" I first argue that a school should be where *heteroglot* cultures, world views, and diverse voices are welcomed, respected, and included. When the formal mathematical activities only emphasize a certain kind of mathematical concept, children might lose opportunities to articulate a variety of informal *heteroglot* mathematical experiences and concepts, even though they are exposed to this *heteroglossia* of mathematics in ordinary experiences. Children are subordinated in pre-tailored school mathematics, while losing their abilities to vitalize their meaningful *heteroglot* mathematics in their lives. This does not mean there should be no *unitary language*—centralized and unified school mathematics curriculum. The tension-filled dynamic of culture is rather a natural phenomenon. It means that schools should revive their nature of *heteroglossia* and be open to children's diverse world views, informal experiences, and voices. When schools are opened to diverse *heteroglot* cultural voices, the centralized *unitary language* would be able to overcome possible risks of cultural narrowness and stagnancy and of alienating potential values. Second, children should be invited to join in the *dialogic living discourses* in the classroom in order to revive meaningful learning and their rights to share their thoughts and to respond to others' words. More specifically, classroom discourses should be reflective of the concrete temporal and special contexts and have a certain story-line. This discourse includes not the decontextualized but the contexualized knowledge. Then, children attain their agencies in school discourse, and school discourse would gain "the dynamic flow of generative process" (Volosinov, 2000, p. 78). Through a true dialogic living discourse, "[school] language acquires life and historically evolves precisely here, in concrete verbal communication" (Volosinov, 2000, p. 95).

WHOLE NUMBER AND OPERATION CONTENT KNOLWEDGE OF PRESERVICE K-8 MATHEMATICS TEACHERS: A SYNTHESIS OF RESEARCH

Eva Thanheiser
Portland State University
evat@pdx.edu

George J. Roy
University of South Florida St. Petersburg
royg@mail.usf.edu

In this report we summarize part of a recent effort to synthesize the state of knowledge of preservice elementary teachers (PSTs') subject matter knowledge and the development thereof. This research was conducted by a recent PME-NA Working Group across all content areas, in this report we focus on whole number and operation. Our review of the literature resulted in only 12 papers drawn from research and practitioner journals and 4 conference proceedings. The scarcity of research on PSTs' subject matter knowledge and the development thereof was characteristic across content areas. The few studies that we found reported that PSTs enter and exit our teacher education programs with weak conceptions in whole number and operations and illuminate the need for further research to (a) better understand PSTs when they enter our programs and (b) better understand how PSTs' conceptions develop.

Introduction & Rationale

Consider a PST solving 527 – 135 (see Figure 1) using the standard algorithm and explaining regrouping as follows:

> You put a 1 over next to the number and that gives you ten. … I don't get how the 1 can become a 10. One and 10 are two different numbers. How can you subtract 1 from here and then add 10 over here? Where did the other 9 come from?"

This PST clearly solved the problem correctly and got the right answer, but was not able to provide an explanation for why this solution method results in the correct answer.

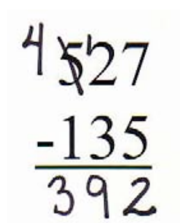

Figure 1: One PSTs' explanation of regrouping in 527 – 135.

Now consider another PST's reflection on her inability to explain regrouping:

> I learned [at the beginning of my elementary mathematics methods class] that there was a lot more to the concept [of number and place value] than I was aware of. I am able to use math effectively in my everyday life, such as balancing my checkbook, but when I was presented with questions as to why I carry out such procedures as *carrying*[1] and *borrowing* in addition and subtraction, I was stuck. I could not explain why I followed any of these procedures or rules. I just knew how to do them. This came as a huge shock

[1] Note that students in the United States often term regrouping in the context of addition *carrying*

> to me considering I did well in most of my math classes. I felt terrible that I could not explain simple addition and subtraction.

Both of these PSTs have determined that they want to teach children, however at this point neither of them would be able to conceptually help an elementary-aged child make sense of why regrouping works when using the standard algorithms taught in the United States.

At the core of elementary school mathematics is the teaching of number concepts and operations. The National Council of Teachers of Mathematics (NCTM) stressed that all pre K-12 students should: (a) understand numbers, ways of representing numbers, relationships among numbers, and number systems; (b) understand meanings of operations and how they relate to one another; and (c) compute fluently and make reasonable estimates (NCTM, 2001, p. 32). A conceptual understanding of number and operation underlies all future mathematics (and other STEM fields) learning. “Number pervades all areas of mathematics. The other four Content Standards [other than Number and Operations] as well as all five Process Standards are grounded in number.” However, research has shown that elementary teachers and PSTs in the United States and Australia continue to lack a conceptual understanding of number concepts and operations (Ball, 1988/1989; Ma, 1999; Southwell & Penglase, 2005; Thanheiser, 2009a, 2010). To be in a position to help PSTs develop more sophisticated conceptions we (mathematics educators) need to understand the conceptions with which the PSTs enter our classrooms so we can build on those conceptions (Bransford, Brown, & Cocking, 1999). As the authors of *The Mathematical Education of Teachers* suggest, “The key to turning even poorly prepared prospective elementary teachers into mathematical thinkers is to work from what they *do* know” (CMBS, 2001). Recent efforts have highlighted the need for teachers to have a deep and multifaceted understanding of the mathematics they teach (Hill, Ball, & Schilling, 2008; Ma, 1999). Less clear, however, is how this teacher knowledge is established.

In our synthesis work we thus examined the current state of knowledge in the field of mathematics education on (a) what we know about PSTs conceptions and the development thereof from research (focus on whole number and operation for this paper) and (b) identify further research needs on what we still need to know about PSTs conceptions and the development thereof.

Methods

We began our synthesis effort by breaking into content groups. Each content group followed the same search criteria. We began by searching ERIC with the search terms listed in *Figure 2.* We limited the search to the years 1998 – 2010 to get an overview of what research occurred during those years. Each combination of search terms was entered into the ERIC data base. All results were checked for a focus on preservice elementary teachers’ content knowledge of whole numbers and operations. We read the title and abstract to determine whether the paper fit our criteria. If the title and abstract did not suffice to make a determination of fit, we read the whole paper. We included all papers that:

- Focused on our target group – *preservice elementary teachers*.
    - We included preservice middle school teachers as well as some certification programs that focus on K-8, since not all countries follow the same school system. By doing so we also determined a student’s age range from 5 years to 12 years (possibly 14 years). As a result, we excluded papers focusing on high school teachers.

  - We included papers focusing on both pre- and in-service teachers (i.e. mixed groups) but excluded papers focusing only on in-service teachers.
- Focused *on content knowledge* of *whole numbers*. We included papers that focused on whole numbers as well as other topics. We excluded papers that focused on beliefs or general content knowledge.
- Published research studies in peer reviewed research journals [for the purpose of this report we are including papers published in PME-NA conference proceedings and research papers published in practitioner journals]. We included all research studies published in peer-reviewed research journals. In the end, we excluded all papers that were not research studies.

Search Terms Round 1		**Search Terms Round 2**
preservice + whole number	preservice + algorithm	elementary education + whole number
prospective + whole number	prospective + algorithm	teacher + number sense
preservice + operation	preservice + multidigit	student teacher + mathematics + number
prospective + operation	prospective + multidigit	teacher + whole number
preservice + place value	preservice + whole number	
prospective + place value		

Figure 2. Search terms for whole number group.

Round 1 initially resulted in 22 studies. Round 2 of our search resulted in no additional studies. After exclusion criteria were applied, we were left with 16 studies. These studies were entered into a database listing the reference, content area, research questions, study type, research design, lens or approach used, selection criteria, description of participants, conditions of and procedures for data collection, data analysis, findings, and conclusions/implications. At least 2 researchers met to discuss in-exclusion of papers and determine the entries into the database. All disagreements about in-exclusion into the database were resolved through discussion.

Results

With Number being such a pervasive topic in elementary school mathematics, surprisingly few papers have focused on PSTs' conceptions of whole numbers. A review of the research literature on preservice teachers' understanding of whole numbers resulted in 12 papers drawn from research journals and 4 from conference proceedings.

Of the research papers reviewed, three categories emerged. The first contained two research studies focused on conceptual aspects of understanding numbers (Thanheiser, 2009a, 2010) and four on the development thereof (McClain, 2003; Mills & Thanheiser, 2010; Thanheiser, 2009b; Thanheiser & Rhoads, 2009). The focus of the second group of research papers consisted of three studies on alternative computational algorithms (Harkness & Thomas, 2008; Lo, Grant, & Flowers, 2008; Nugent, 2007). The final grouping included two studies on number sense (Tsao, 2005; Yang, 2007), two studies on understanding operations and order of operations (Chapman, 2007; Glidden, 2008), one study about PSTs' struggle with number concepts (Southwell & Penglase, 2005), and one study on manipulatives usage (Green, Piel, & Flowers, 2008). Below we briefly describe each of these categories beginning with papers focusing on PSTs' conceptions of number and the development thereof.

PSTs' Conceptions of Number and the Development Thereof

Two papers focused on PSTs' conceptions of number. Thanheiser (2009, 2010) examined PSTs' conceptions of number and identified and categorized PSTs' conceptions of multidigit whole numbers into four major groups: thinking in terms of (a) *reference units*, (b) *groups of ones*, (c) *concatenated-digits plus*, and (d) *concatenated-digits only*. See Table 1 for the definition and distribution of the conceptions among the PSTs in that study.

Table 1 *Definition and Distribution of Conceptions in the Context of the Standard Algorithm for the 15 U.S. PSTs in Thanheiser's Study*

Conception	# of PSTs
1. *Reference units.* PSTs with this conception reliably[2] conceive of the reference units for each digit and relate reference units to one another, seeing the 3 in 389 as 3 *hundreds* or 30 *tens* or 300 ones, the 8 as 8 *tens* or 80 *ones*, and the 9 as 9 *ones*. They can reconceive of 1 *hundred* as 10 *tens*, and so on.	3
2. *Groups of ones*. PSTs with this conception reliably conceive of all digits correctly in terms of groups of ones (389 as 300 *ones,* 80 *ones*, and 9 *ones*) but not in terms of reference units; they do not relate reference units (e.g., 10 *tens* to 1 *hundred*).	2
3. *Concatenated-digits plus.* PSTs with this conception conceive of *at least one* digit as an incorrect unit type at least on occasion. They struggle when relating values of the digits to one another (e.g., in 389, 3 is 300 ones but the 8 is only 8 ones).	7
4. *Concatenated-digits only*. PSTs holding this conception conceive of *all* digits in terms of *ones* (e.g., 548 as 5 *ones,* 4 *ones*, and 8 *ones*).	3

Thus, Thanheiser (2009a) found that 2/3 of the PSTs in that study saw the digits in a number incorrectly in terms of ones at least some of the time. In follow up studies Thanheiser (2010) further examined the PSTs' interpretations of regrouped digits and refined the *concatenated-digits plus* conception into three further categories:

a. Regrouped digits consistently explained as 10 (regardless of whether it is in the context of addition or subtraction),
b. Regrouped digits explained consistently depending on context (i.e., 10 in subtraction, 1 in addition or vice versa)
c. Changed interpretations of the regrouped digit depending on the question posed (i.e., regrouped 1 in the ten's place in the context of addition as 10 or 1 in different tasks).

In this study, 3 of 33 PSTs were able to correctly explain the values of the regrouped digits in the in both addition and subtraction contexts and 5 PSTs saw the values of all regrouped digits as 1 – consistent with the concatenated digits conception. The distribution of the remaining 25 PSTs who fell into the concatenated digits plus category can be seen in Table 2.

Three studies focused on the development of PSTs' conceptions (Mills & Thanheiser, 2010; Thanheiser, 2009b; Thanheiser & Rhoads, 2009). Thanheiser & Rhoads (2009) found that exploring the Mayan numerals (understanding/reading numbers and inventing algorithms for addition and subtraction) helped PSTs explicate the structure of the base-ten system. This allowed PSTs who typically used the terms "tens" and "hundreds" etc. as labels rather than

[2] *Reliably* in these definitions means that after the PSTs were first able to draw on a conception in their explanations in a context, they continued to do so in that context.

quantities to move beyond labels and consider the quantities each digit represents. By working with a number system with which they are less comfortable, PSTs were able to explore the meaning of a place-value system. In another study Thanheiser (2009b) explored the development of PSTs' conceptions in a teaching experiment setting and found that simply exposing students to correct conceptions (telling them the meanings of the digits) does not necessarily help them develop such conceptions. And even though PSTs may sit in a classroom in which alternative methods are explored and made sense of, they may do so in a perfunctory manner. They may cling to the standard algorithms (possibly without making sense of it) as superior methods of solving problems. To allow those PSTs to move beyond the standard algorithms we need to expose them to problems with the standard algorithms and with seeing each digit as representing ones. This can be done by introducing artifacts of children's mathematical thinking to highlight these shortcomings (Thanheiser & Mills, 2010).

Table 2 *Conceptions of the 33 PSTs in the Context of Standard Algorithms (Detailed)*

<table>
<tr><th>Conception across addition and subtraction tasks</th><th>Number of PSTs</th></tr>
<tr><td>One of the two correct conceptions (reference units or groups of ones</td><td>3</td></tr>
<tr><td>Concatenated digits plus
<table>
<tr><td>Refined Conception</td><td>Number of PSTs</td></tr>
<tr><td>Regrouped digits consistently explained as 10 (regardless of whether it is in the context of addition or subtraction)</td><td>7</td></tr>
<tr><td>Regrouped digits explained consistently depending on context (i.e., 10 in subtraction, 1 in addition or vice versa)</td><td>10</td></tr>
<tr><td>Changed interpretations of the regrouped digit depending on the question posed (i.e., regrouped 1 in the ten's place in the context of addition as 10 or 1 in different tasks).</td><td>8</td></tr>
</table>
</td><td>25</td></tr>
<tr><td>Concatenated digits only</td><td>5</td></tr>
</table>

McClain (2003) examined the development of PSTs' conceptions of place value and found that research on children's development of conceptions can support the PSTs' development. She stated, "This finding also has broader implications—that the broad base of research conducted in elementary classrooms can feed forward to inform efforts at supporting the development of preservice teachers' content knowledge" (p. 301). As a result, PSTs also came to a realization that in order to teach for conceptual understanding, they themselves would need to possess this type of understanding.

PSTs' Working with [Alternative] Algorithms for Basic Operations

Three papers focused on exploring PSTs' working with alternative algorithms. Harkness and Thomas (2008) found that PSTs' understandings of invented algorithms is more procedural than conceptual. They found that getting at the mathematics is difficult and learned that if they expect PSTs to write about the mathematics they must explicitly ask them to do so. Lo, Grant, & Flowers (2008) found that teachers' ability to develop and justify reasoning strategies for multiplication develops slowly. They found that PSTs struggled recognizing the difference between procedural and conceptual descriptions of solutions to multiplication problems. They also found that PSTs struggled coordinating the area/array interpretations as well as the equal groups interpretation with various strategies for multiplication. It was not clear whether students needed more time or different kinds of experiences to continue to develop this understanding. As a result, the authors suggest more research be conducted to investigate this. They also emphasized that we need to highlight the "ineffectiveness of memorizing and applying rules/procedures without understanding why they work" (p. 20). Nugent (2007) also concluded that teachers need to understand why an algorithm works and how the arithmetic extends to algebraic procedures while exploring the lattice methods.

PSTs' Understanding of Number Sense and Number Concepts and Addressing Misconceptions with Manipulatives.

Two papers focused on number sense (Tsao, 2005; Yang, 2007) and one on number concepts (Southwell & Penglase, 2005), one on operations (Chapman, 2007) and one on order of operations (Glidden, 2008).

Tsao and Yang both found that PSTs, especially the ones who struggled, focused on procedures rather than number sense when solving problems. Tsao found that many PSTs are not ready to be immersed into a curriculum that reflects the vision of less emphasis on paper-and-pencil computation and more emphasis on number sense and mental arithmetic, as stated in the NCTM Standards. The data indicates that the high ability students were more successful on each type of number sense item than the low ability students. Compared to high ability students the low ability students in this study (a) tended to use the rule-based method more frequently when answering interview items and (b) preferred the use of standard written computation algorithms rather than the use of number sense based strategies. The high ability students tended to use benchmarks, to apply "number sense" based knowledge. Yang examined the following four categories: (1) understanding the meanings of numbers, operations, and their relationships, (2) recognizing relative number size, (3) judging the reasonableness of a computational result by using strategies of estimation, and (4) developing and using benchmarks appropriately. He found that for each category, about two thirds of participants relied on rule-based methods to answer the questions. Thus, procedural thinking seemed to be a powerful method of approaching problems especially for low ability students.

Southwell and Penglase focused on number concepts. In the whole number area they examined basic concepts (numeration), basic facts, four basic operations, order of operations, and word problems. They found that place value concepts seem to have caused the most difficulty in their survey of various number concepts, however, PSTs performed poorly across tasks. Chapman focused on operations and found that PSTs' initial knowledge of arithmetic operations was inadequate to teach conceptually and in depth. Glidden focused on order of operations and found that PSTs hold superficial knowledge of the order of operations.

Thus PSTs tend to approach problems procedurally because they lack a conceptual understanding of place value, operations, and order of operations.

One paper focused on addressing PSTs' misconceptions with the use of manipulatives. Green, Piel, & Flowers (2008) explored the use of manipulatives and found that manipulative-based instruction resulted in statistically significant decreases of arithmetic misconceptions and statistically significant increases of arithmetic knowledge, with respect to the basic operations. They state that manipulatives can effectively reverse most arithmetic misconceptions of PSTs and that the same activities used to reverse misconceptions can also improve the accuracy and depth of arithmetic knowledge. Thus, they conclude, manipulatives can and should be used effectively in PST classrooms.

Discussion/Conclusions

So What Can We Say?

In our synthesis of research, three distinct categories examining PSTs' content knowledge of whole numbers emerged. The categories include PSTs': (a) conceptions of whole number concepts and development thereof; (b) working with alternative algorithms for basic operations; and (c) understanding of number sense and number concepts. The results are promising. However, given the dearth of research published in peer-reviewed research journals during the last ten years, it has been determined there is still a need to examine PSTs' development in this content area. As exemplified by the two prospective teachers highlighted in the introduction of this paper, prior research has documented that PSTs heavily rely on memorized procedures in the content area of whole numbers and operations. In addition, many PSTs struggle to conceptually explain why the procedures work. Whereas, some research has been conducted on examining how we (mathematics educators) can help these PSTs develop more sophisticated conceptions, there is still much work is left to do for us (mathematics education community) to fully understand how PSTs concepts develop and how this development can be facilitated. This may be accomplished by conducting research in our teacher preparation courses to address the conceptions and misconceptions preservice teachers have when learning whole number concepts. For example, having PSTs explore whole number concepts in numeration system other than base-10 may provide the cognitive dissonance needed for more mathematics educators to research PSTs' development of whole number concepts in a meaningful way.

We juxtapose the history of integers with current pedagogical approaches. We also present findings concerning children's reasoning about negative numbers prior to instruction. We see alignment between children's intuitions and the avenues that afforded progress for mathematicians, while the textbook approaches tend to run counter to lessons learned from history.

Introduction

The introduction of the notion of signed numbers is a critical point in children's learning of mathematics. As with fractions, the advent of integers widens the domain of numbers in children's mathematical worlds and, as such, presents notorious difficulties. Some of the challenges that children experience in coming to grips with the notion of negative numbers parallel those that mathematicians encountered historically. On the other hand, the experience of most children today as they learn about integers is quite distinct from that of mathematicians of old. After all, at the time when Diophantus was denying the possibility of negative solutions to linear equations – a position that was perfectly reasonable based on his conceptions of number – he had no teacher or textbook telling him otherwise (Gallardo, 2002; Henley, 1999).

We looked to the history of integers to guide our review of current textbook approaches to integer instruction. The juxtaposition of these two bodies of evidence raises questions about the utility of prevalent textbook approaches. At the same time, we have seen children in interviews engage productively with ideas concerning positive and negative numbers prior to formal instruction. These findings suggest potentially fruitful alternative directions for textbook instruction concerning integers.

Theoretical Framework: A Historical Perspective

Before there were positive and negative numbers, there were simply numbers. The notion of *positive* is only meaningful in contrast with *negative*. Thus, the history of integers is largely the history of negative numbers. Negative numbers arose from the operation of subtraction, and they came about in at least two ways:

1. There is sense in which a subtrahend can be regarded as a *subtractive number* (Henley, 1999), which is to say that the subtraction operation is subsumed into the quality of the number. For example, instead of interpreting the expression 9 – 5 as meaning that we subtract 5 from 9, we might instead think in terms of 9 and "subtract 5" being combined additively. Under this interpretation, "subtract 5" becomes an entity that we can think about, even in the absence of any particular minuend. We can reason about -5 without

having a notion of this entity as a negative number, but simply as an amount to be taken away. Thus, 3 – 8 = -5 since we still must take 5 more away.

2. The natural numbers are not closed under subtraction. We must either restrict subtraction to cases in which the minuend is greater than or equal to the subtrahend, or we must confront situations in which the subtrahend is greater.

Negative numbers, or at least their ancestors, arose for mathematicians in these ways. For centuries, mathematicians struggled to make sense of such numbers by relating them to quantities. Some real-world situations were amenable to interpretation in terms of positives and negatives, while in other cases negatives were nonsensical (Colebrooke, 1817; Henley, 1999).

The history of negatives is a history of progress in the face of resistance. The mathematical machinery continued to be developed even as mathematicians held negatives in dubious regard, and some objected vehemently to their use. Resistance derived from legitimate paradoxes: How is it possible to take something from nothing? How could -7 be “smaller” than 3, let alone 0? Such questions plagued great thinkers and stymied progress (Hefendehl-Hebeker, 1991). Nonetheless, over time, more and more mathematicians used and came to embrace negatives because of their usefulness. The resistance to negatives stemmed from attachment to concrete or quantitative interpretations of number. Acceptance followed from an alternative, purely mathematical stance: Negative numbers were legitimate because they solved uniquely mathematical problems, not because they were necessary for solving problems concerning money, elevation, temperature or any such thing, and not because they made sense in all the same ways that that regular (non-negative) numbers made sense. Ultimately, it was the advent of abstract algebra that led the mathematical community to fully accept negatives as numbers, on par with positives. The integers came to be recognized as a domain, distinct from other domains such as the natural numbers, and it was unproblematic for different domains to have different properties (Henley, 1999).

Children’s Introduction to Integers

The extension of the natural numbers poses challenges for both teachers and students. Children are expected to expand their mathematical worlds to include negative integers and (non-negative) rational numbers, on the way to real numbers (Bruno & Martinón, 1999). These extensions challenge students’ previous conceptions, which often involve overgeneralizations of their experiences with the natural numbers. There is a wealth of research concerning teaching and learning in the rational number domain (e.g., Empson & Levi, 2011; Fosnot & Dolk, 2002; Lamon, 1999; Sowder, 1995). However, few reports exist that address the challenges of students’ learning about integers (Kilpatrick, Swafford, & Findell, 2001).

Integers and integer operations present conceptual difficulties for students (Janvier, 1983; Vlassis, 2004). These difficulties can be appreciated in light of the history of mathematics, wherein mathematicians struggled with counterintuitive notions associated with negative numbers (Henley, 1999; Gallardo, 2002; Thomaidis & Tzanakis, 2007). Mathematicians of old struggled with the distinction between magnitude and order that arises with negatives: There is a sense in which -7 is more than 3; however, it comes before 3 on the number line, and we use the term “less than” to refer to this relationship. Children encounter these same issues when introduced to negative numbers. However, our world has changed such that mathematically literate adults today can take negative numbers for granted. Thus, teachers may treat the introduction of negatives matter of factly, whereas for children it involves a conceptual revolution.

It was only after considerable conceptual struggles that great mathematicians such as Descartes and Newton came to accept negatives as numbers. It is no wonder, then, that children would face difficulties in making sense of negative numbers and operations involving them. At the same time, however, researchers have found children to be capable of reasoning about integers in relatively sophisticated ways, even in the lower elementary grades (Behrend & Mohs, 2006; Bishop, Lamb, Philipp, Schappelle, & Whitacre, 2011; Hativa & Cohen, 1995; Wilcox, 2008). For example, Bishop et al. found that first graders who had never heard of negative numbers nonetheless began to invent and reason productively about them in the contexts of playing a number line game and solving open number sentences.

Methods

There are three branches of this study: historical review, textbook analysis, and analysis of children's thinking. In this section, we discuss our methods of data collection and analysis with respect to each of these three branches.

Historical Review

We reviewed sources concerning the history of mathematics with a focus on ideas associated with negative (and positive) numbers, especially the integers. We identified in the literature aspects of the extension to negatives that troubled mathematicians, as well as trends and insights that led to the acceptance of negatives as numbers. These findings further informed our analysis by providing a lens through which both the textbook approaches and children's reasoning could be interpreted.

Textbook Analysis

We analyzed the treatment of integer topics in 18 fifth- and sixth-grade mathematics textbooks currently adopted by the State of California. Our methods of analysis were both quantitative and qualitative. We counted the numbers of textbooks employing particular approaches or types of problems, so that descriptive statistics would provide a sense of the frequency of these approaches. We focused our analysis on those chapters/sections of textbooks devoted to integers directly – those lessons concerning what integers are and how to operate with them. Our qualitative analysis of the textbook content began with a process of open coding (Strauss & Corbin, 1998). We used principles of grounded theory (primarily the constant comparative method) to identify emergent, distinguishing themes and features of how integers are presented in textbooks (Strauss & Corbin, 1998). We balanced emergent codes from the data itself with historical and theoretical findings from the literature. We report on trends seen across the sample of textbooks and highlight pedagogical issues that stand out to us. In particular, we examine these textbook approaches through a lens informed by the history of integers.

Analysis of Children's Thinking

We conducted interviews with 55 elementary school students from Texas and California. Twenty-nine of these children were in grades K-2 at the time of the interviews; the rest were in grades 3-5. The responses that we discuss in this paper were to open number sentences, such as the problem $3 - 5 = \square$. These were used with interview participants at all grade levels because, whether or not K-5 children have been introduced to negative numbers, the question is at least sensible. They are familiar with the natural numbers and with subtraction. Those children who did have some familiarity with negative numbers were posed problems that explicitly involved negatives, such as $-5 + -1 = \square$. The interviews themselves were conducted at the children's school sites, during the school day. They lasted between 30 and 50 minutes and were videotaped.

Our analysis of the videotaped interviews was qualitative, focusing on children's solution strategies as well as their underlying ways of reasoning. Through constant comparative analysis, we identified various themes concerning students' reasoning about integers. We then related these to the history of mathematics, identifying parallels in the form of obstacles to progress in dealing with negative numbers, as well as ways of thinking that afforded innovations. In this short paper, we highlight certain productive ways of reasoning.

Results: Textbook Approaches to Integer Instruction

A hallmark of current textbook approaches to the teaching of integers is the use of contexts and models. The most typical contexts used in textbook presentations of the integers themselves or of addition or subtraction involving integers are the following: money (used in 94% of the textbooks sampled), elevation (89%), temperature (89%), and movement forward and back (61%). The typical models employed in instruction involve (1) number lines and (2) colored chips (or, in some cases, "charged particles") that are used to represent positive ones and negative ones. An example of the use of a money context would be a person's bank account balance and how it is affected by one or more transactions. The following story problem and example solution appear in the integer addition section of a sixth-grade textbook:

> The Debate Club's income from a car wash was $300, including tips. Supply expenses were $25. Use integer addition to find the club's total profit or loss.
>
> 300 + (-25) *Use negative for the expenses.*
> 300 – 25 *Find the difference of the absolute values.*
> 275 *The answer is positive.*
> The club earned $275. (Burger, Bennett, Chard, Jackson, & Kennedy, 2007)

Perhaps the most poignant theme concerning story problems related to integers is that these tend to be quite accessible without the use of negative numbers. In fact, problems in real-world contexts can be solved without invoking negatives, and this generally seems to be more natural. For example, in the Debate Club problem above, the use of integers is entirely unnecessary. The debate teamed earned $300 from a car wash, and they spent $25 on supplies. So, their profit is $300 - $25 = $275. The only reason to represent this situation as involving addition of a negative, rather than whole-number subtraction, is the book's instruction to do so. (In fact, the same story problem would be identified as a subtraction problem if it appeared in a second- or third-grade textbook.) Furthermore, even when the problem is framed as involving the addition of two integers, the way that this "addition" is performed is to subtract!

The character of the role of the context here is not that integers are useful for solving problems in certain contexts. Rather, the message we get is that there are contexts than *can* be described in terms of integers if we choose to do so. In other words, integers do not appear as tools that are necessary for solving problems in the world, but as an artificial, purely mathematical lens that we can apply to real-world contexts when that is the game to be played. We note that this is not merely a matter of poorly chosen story problems. Two years into a project concerning integers, our team has yet to identify a real-world context that actually requires one to use negative numbers. When one considers that Greek mathematicians, for example, solved a wide variety of real-world problems without the use of negative numbers, the lack of appropriate contexts for which negative numbers are necessary seems less surprising.

In most textbooks, students are expected to translate a story problem into an expression involving integers (as in the example above) and then to evaluate that expression by appealing to sign rules or to a procedure associated with a prescribed model. That is, we do not see students' intuitions about the contexts being tapped to guide solution strategies (beyond the task of translating to a number sentence). Furthermore, it is difficult to find power in the rules that students are expected to use to evaluate integer expressions. While algebraic equations may enable students to solve problems that they could not solve otherwise, number sentences involving integers represent extra work required of students in the name of solving otherwise readily accessible tasks.

We do not mean to suggest that the only reason to relate integers to contexts would be that they provide indispensable tools for solving problems. There could be legitimate pedagogical purposes for doing so. Certainly, experts in reasoning about integers are capable of relating them to real-world contexts. However, in our review of textbook treatments of integer topics, we have found that these contexts tend to be used in a contrived fashion that may undermine the utility of the integers *within* mathematics.

Children's Intuitions about Integers

We look to interviews with elementary children to reconsider opportunities for learning about negative numbers. We have seen powerful examples of children reasoning about positive and negative numbers prior to formal instruction about integers. We discuss the reasoning of two children, a first grader (Jackson) and a fourth grader (Roland), in the context of solving open number sentences. (We use pseudonyms for the children's names.)

Jackson's Reasoning

Jackson, a first grader, had heard of negative numbers and had seen a number line that included some negatives in his classroom. He had received no formal instruction concerning negative numbers. This minimal exposure to the notion of negatives was enough to enable him to extend his counting strategies to the left of zero. For example, Jackson solved $-2 + 5 = \square$ by starting at -2 and counting up five: -1, 0, 1, 2, 3. Although he had not been taught to solve addition problems involving negatives, Jackson's previous experiences with addition enabled him to solve this novel problem.

Early in his interview, Jackson had said that he could not solve problems such as $6 + -3 = \square$. He had no way of making sense of starting with six of something and then adding negative three. However, following Jackson's solution above ($-2 + 5 = 3$), he was presented with $5 + -2 = \square$. Based on his answer that $-2 + 5 = 3$, Jackson concluded that $5 + -2$ also equaled 3, explaining (in the language of a first grader) that the results must be the same due to the commutative property of addition. When asked what $5 + -2$ meant, Jackson decided that it meant the same as subtraction since $5 – 2$ was also 3. He went on to solve the problem $6 + \square = 4$ by thinking about how much he would have to subtract from 6 to get 4.

Roland's Reasoning

Roland was in fourth grade. Like Jackson, he had heard of negative numbers but had not received formal instruction concerning operations involving them. Nonethless, Roland reinvented common sign rules for addition and subtraction of integers by reasoning about negative numbers as "the opposite" of positives. For example, Roland solved $-5 + -1 = \square$ by reasoning that adding two negative numbers "would make it further from the positive numbers." Since he knew that the sum of 5 and 1 was 6, he reasoned that -5 plus -1 should equal -6. Roland was also able to solve $-5 – -3 = \square$ by building on his previous reasoning. He said, $-5 – -3$ "would probably be… minus two, because if you use addition… it would be farther from positive numbers, so if you do the opposite it should be closer." Roland reasoned that adding -3 to -5 would result in moving futher into the negatives, so subtracting -3 from -5 should result in moving toward the positives instead. The opposite operation had to have the opposite effect.

Mathematical Insights. Jackson had productive insights concerning the properties of integers. He made these by drawing on basic understandings of the natural number domain, together with simple familiarity with the notion of negative numbers as numbers less than, and to the left of, zero. He made progress by reasoning within the realm of mathematics, not by looking outside of it. Similarly, Roland used logic, together with an understanding of + and – as opposites, to effectively reinvent sign rules for addition and subtraction of negative numbers. Middle school textbooks go to elaborate lengths to present these rules in such ways that hopefully students will remember them. Roland, a fourth grader, figured them out for himself.

Roland and Jackson did not make the leaps described above by relating integers to a context or by applying a chip model. Rather, they leveraged logic and familiar mathematical properties to solve novel problems. These moves opened up new possibilities for them. At an elementary level, these children's productive insights echo the work of mathematicians such as Newton who overcame difficulties associated with negatives through a pragmatic approach, driven by mathematical utility and logical necessity.

Implications

In light of the history of the integers, it seems worthwhile to reconsider the ways that contexts and models are typically used in integer instruction. In the history of mathematics, attempts to relate integers to contexts and models both facilitated and constrained progress. The notion of negative numbers arose not out of real-world situations involving directed magnitudes, but from within mathematics itself. Ultimately, mathematicians made sense of and accepted negatives as numbers not because of any relationship to real-world quantities, but on pure mathematical terms. Resistance to negatives was alleviated by a shift in perspective. Mathematicians let go the search for clarifying models and came to view numbers as abstract entities. They recognized that the natural numbers and the integers are distinct domains with different properties, and that the integers are useful for solving mathematical problems (as opposed to story problems).

Our purpose is not to denigrate contexts, models, manipulative materials, or textbooks. On the contrary, when it comes to many topics, we support approaches that relate numbers to quantities. In the case of young children learning to reason in the natural number domain, we see real-world contexts and materials such as Unifix cubes and base-ten blocks as extremely helpful resources. However, integers are different! The notion of a negative number is a strange idea and one that does not correspond well with the experiences of people in the world. Even individuals who have come to accept negative numbers within mathematics tend to regard them as fictitious entities with respect to the physical world. One child that we interviewed described negatives as belonging to a "ghost world" in which faint images of objects could be seen, although the objects were not really there.

It is no wonder that attempts to relate integers to contexts often appear contrived. Why do we insist on such an approach? Consider instead an honest, purely mathematical alternative whereby students are asked to confront issues that were previously swept under the rug: *Why can't we subtract bigger from smaller? What if we could? We can add and multiply without restriction. Suppose that we wanted to be able to subtract and divide with as little restriction as necessary.*

How could we do that, and how might we interpret the results? These are fair, mathematical questions that children are capable of exploring. Rather than think up elaborate ways of getting students to learn and remember the sign rules for operations with integers, we could invite children to establish for themselves what those rules ought to be. Preliminary evidence from interviews suggests to us that children could come to construct the integers from the natural numbers, given appropriate support for doing so.

FROM OPPOSITIONAL CULTURE TO MANIFESTING GOALS: A FRAMEWORK OF RESILIENCE AND GROWTH

Geillan D. Aly

Marcy B. Wood
University of Arizona
mbwood@email.arizona.edu

Using the psychological construct of resilience, we analyze research on mathematics identity, race and ethnicity. Findings in the literature show the existence of a meta-framework, a trajectory from a framework of violence to one of positive growth. The foundational frameworks of Ogbu elucidate the lived adversity whereas later works, such as Nasir, illustrate lived positive responses that promote academic success. Illustrating and supporting studies are included.

Purposes of the Study

The construct of identity has become an important tool for mathematics education research. Many researchers have used identity to make sense of questions about differences in students' mathematical thinking and learning (Author 2, 2008; Boaler & Greeno, 2000; and Oslund, 2010), and especially to consider unyielding questions about differences in mathematical performance across racial and ethnic lines (Jilk, 2007; Martin, 2000; and McGee, 2009). Identity, as a tool, has been used to frame differences in academic performance since at least the 1980's when John Ogbu first wrote about voluntary and involuntary minorities, suggesting that external factors associated with identity contribute to student success. As researchers continue to study race, mathematics, and identity, some have built upon the work of Ogbu (and others), crafting new research trajectories and constructs of identity. The purpose of this paper is to examine changes in these constructs, seeking patterns in the changes and drawing conclusions about them.

As we explored the history and uses of identity that explore mathematics education and race/ethnicity, we were struck by a common trajectory that began with notions of adversity or violence then moved towards a positive adaptation. Foundational frameworks (like Ogbu's) tended to invoke adversity and violence to describe the relationship between racial identity and success and failure in academic mathematics. Subsequent authors seem to build from the premise of violence toward more non-violent framings. Intrigued by this trajectory, we sought framings that might clarify these trends and settled on a framework of resilience. In the next section of this paper, we will elaborate the framework of resilience and then, in our findings, demonstrate how that framework plays out in research on racialized mathematics identity.

Theoretical Framework

Resiliency is a psychological construct that refers to the process of positive adjustment to adverse circumstances. This definition implies two important conditions: exposure to adversity and a positive response (Luthar, Cicchetti, & Becker, 2000). We recognize that it is unusual to draw upon a psychological construct to analyze research; our purpose is not to comment upon the resiliency or psychological condition of any of the authors of the articles we cite. However, we are purposeful in drawing upon the *conditions of resiliency* to make sense of our findings.

Psychological researchers have broadly defined the first condition, exposure to adversity: Adversity can range from traumatic, short-term life events (such as a moment of physical violence) to long-term stressful conditions (such as living in poverty) (Luthar, et al., 2000). This adversity is experiential and includes the history of slavery and other oppressive acts against non-majority peoples as well as current physical and psychological violence resulting from the persistence of racism and segregation in the United States. We use the notion of adversity to examine how research on math identity acknowledges the *lived adversity* (physical and mental) faced by racial and ethnic minorities in the United States. We are also interested in the second condition of resiliency: the *lived positive response*. The positive response suggests the existence of productive activities of racially/ethnically minoritized students as they engage in learning mathematics. For example, as students draw upon the mathematics in their daily lives to make sense of school mathematics, they frame their lived experiences in a positive light and use these experiences as a resource for mathematical learning.

Both *lived* components of the definition of resiliency give rise to *theoretical* constructs. In other words, researchers use *theoretical adversity* to metaphorically frame identity in ways that focus on violence and adversity. One example is Herzig's reference (2004) to the term "egotistical suicide". This theoretical construct is used to describe graduate student attrition in mathematics departments: Herzig suggests that students who voluntarily withdraw from the mathematics community are committing "suicide". By purposefully using this term, Herzig situates her theoretical framework in the context of violence and adversity. Herzig's use of suicide is an example of what we are calling *theoretical violence*.

The *lived positive response* also has a theoretical counterpart, the *theoretical positive response.* Researchers who use a theoretical positive response frame race and identity in ways that focus on positive, productive adaptations. For example, the work on Funds of Knowledge (Moll, Amanti, Neff, & Gonzalez, 1992) starts with an orientation toward experiences and background as cognitive resources that can support academic success.

It is our assumption that researchers use the lived adversity and lived positive responses of involuntary minorities to inform their theoretical framings of identity in their study of student achievement in mathematics. Although these researchers acknowledge the violence experienced by minority communities, some decentralize the lived adversity within these communities and celebrate the potential therein. In our findings, we offer a limited exploration of how adversity appears in research on race, identity, and mathematics education and explore an evolution in the literature that demonstrates a positive response in the portrayal of the minority student.

Methods

We performed a comprehensive search for articles on mathematics identity. We utilized the following search engines: JSTOR, ERIC, EBSCO, PsycINFO, Social Sciences Citation Index, ProQuest, and Sociological Abstracts. Approximately 1,200 citations were compiled using search terms such as "mathematics identity, education" and "math*, identity, education". The term "education" was included to eliminate extraneous articles that focus on the mathematical use of the word identity. A hand search completed this phase with the help of Google Scholar.

These 1,200 citations were refined to remove duplicates and irrelevant articles. For example, we removed articles on STEM (science, technology, engineering and mathematics) majors, cognitive science, and articles on academic identity with little mention of mathematics. Finally, we removed articles in languages other than English. This reduced the list to 303 papers.

Next, the articles were categorized into groups such as gender, race/ethnicity, and teacher identity. Sixty-nine articles were categorized under race/ethnicity. Articles where identity was not central were then eliminated. For example, we did not include articles that addressed the mathematical achievement gap among ethnicities but did not expressly invoke identity. A clear framework or definition of identity was not required since some authors' definition of "efficacy" or "goals" resembled other's definition of "mathematical identity". Finally, dissertations were removed. This left a final count of sixteen articles to analyze.

We examined these articles by mapping and exploring commonalities and differences across theoretical frameworks, the definition of mathematical identity, problem construction/resolution, and citations. We noticed violence used as a theme in some foundational articles and observed that violence or nonviolence arose as researchers built upon these foundational pieces. Our findings elaborate on the use of violence and the movement away from it. We include the articles that best illustrate our observations on the theoretical construct of resilience and its implications.

Findings

John Ogbu, Involuntary Minorities, and a Culture of Opposition

Several mathematics education researchers build from the foundational frameworks of John Ogbu (e.g. Martin, 2000; Nasir, 2002; and Stinson, 2008). Ogbu's work (1987, 1992, and 1998) acknowledges the lived violence of minority people and reflects that violence in his theoretical framework. His theoretical differentiation of involuntary and voluntary minorities arises from differences in their experiences of lived violence in the United States. Involuntary minorities are non-immigrant minorities whose ancestors have been enslaved, conquered, or colonized and who have been made members of American society against their will. Thus, the category of involuntary minority is predicated on this history of violence. In contrast, voluntary minorities emigrated from their homeland to the United States in search of greater opportunities (Ogbu & Simons, 1998). Because of their recent arrival, voluntary minorities lack the same legacy of violence (in the United States) as involuntary minorities and they see their presence in the United States optimistically and not dictated by the government or the White[1] hegemony. This does not imply that voluntary minorities have had no exposure to violence – Ogbu's framework emphasizes the contrasts between the lived experiences of minorities in the "adopted" country.

Ogbu draws upon the differences in lived violence to account for variation in academic performance between these two groups. The violent sociohistorical legacies and lived adversities of involuntary minorities cause them to develop an identity opposing that of White America's middle-class. This *oppositional culture* counters the hegemonic group by redefining the values placed on role models, paths to economic, social and academic success and government-controlled institutions. As a result, based on the rejection of school, a White institution, involuntary minority parents give their children contradictory signals on the value of knowledge; they value education but reject the institution of school (Ogbu & Simons, 1998).

Ogbu also develops a framing of three influencers that contribute to academic failure among minorities: society, school, and community (Ogbu, 1987). These influencers are affected by and contribute to the lived adversities of involuntary minorities. Societal traditions of denying lucrative jobs and equal opportunities (in vocation and education) teach involuntary minorities that personal investment in education will not yield the expected results, and thus contribute to lived adversities. Likewise, schools, a reflection of the larger society, contribute to lived adversities when they prevent minority students from receiving an equitable education. Finally the communities who take up the oppositional culture contribute to failure by sending the message that academic success is success in a White institution and therefore undesirable.

The lived adversity seen in the language of opposition and conflict is felt in some studies that build on Ogbu's theoretical framework. Lim (2008) analyzed the school mathematics experiences and illustrated the lived adversity of two Black sixth-grade girls. One student, Stella, had a naturally boisterous, outgoing spirit but became shy, subdued and deeply self-alienating in her mathematics class. This was due to her knowledge of the simultaneous existence of two conflicting worlds within the school, the academic world and the social African-American world. Stella's parents reinforced this conflict by encouraging her to succeed but sharing anecdotes of failure in mathematics based on theirs and others' lived adversities. The conflict between socially conforming and learning mathematics led to indecision between studying pre-algebra and rejecting social alienation. Stella's understanding of how these diverging cultures clashed, suppression of her academic desires and opposition to the academic, White, world returns us to Ogbu's framing of identity based on adversity and oppositional cultures. Stella not only regarded the culture of her mathematics class as oppositional and violent, but she labeled it dangerous.

Lim's second student, Rachel, offers a slightly different enactment of oppositional culture. Rachel did not compromise her identity in the mathematics classroom and excelled in class. She routinely completed her class work early but was never made aware of challenging mathematics tracks. Rather than consider a "White", hegemonic track to academic success, Rachel looked to the defined oppositional path, sports, as the best way to meet her life's goals. Although Rachel discussed the importance of education, she visualized her world through a lens of opposition that does not see the value and potential in her work as a scholar. To both girls, school was not an area to grow and thrive; it was an arena of conflict. Both girls were candidates for pre-algebra but neither placed in that course and thus were limited by responses to their lived adversity.

Ogbu's frameworks respond to the violent lived adversities of African-Americans. In violent or threatening academic settings, students isolate themselves and do not consider positive effects of the academic world. Ogbu's frameworks are critical because they clearly acknowledge and proclaim the role of violence and adversity in minority students' (lack of) educational opportunities. This acknowledgement provides the essential foundation for subsequent frameworks that, to borrow from Dr. Martin Luther King, Jr., "hew out of the mountain of despair a stone of hope" (1963). The next two sections explore how researchers have leveraged Ogbu's affirmation of violence to "hew… a stone of hope" and construct new insights into the mathematical learning of minority students.

Moving from Violence toward Positive Adaptation

While researchers who study ethnicity and race in mathematics education cannot ignore the lived adversity of involuntary minorities, some developed frameworks that recognize but lead away from violence. Martin's work (2000) on African-American students' mathematical identity uses Ogbu's work to link identity and mathematics learning and establishes the importance of racialized experiences in the mathematics classroom. Martin expands Ogbu's school and societal influences (Ogbu, 1987) on the failure in academic mathematics among Black students to include success. Martin acknowledges the opposition and lived adversity of African-Americans but also adopts a stance that moves away from violence by analyzing Ogbu's influencers for success factors and lived positive responses, shifting his framework towards resilience.

Martin finds that African-American students who succeeded in academic mathematics resisted or opposed influences seen by them as negative, whether from Black or White society. They took ownership of their academic development but experienced social pressures as a result. Teasing, ridicule, and severe taunting by their African-American peers ostracized students for their achievements. This tension reflects Ogbu and Simons' ideas (1998) on the discord that occurs when a student thrives in the White academic world. Yet these students react to their lived adversities by succeeding academically, a move, which can be seen as a positive response.

Martin notes the lack of research on the successes of African-Americans and indicates that much can be learned from understanding how positive responses can develop from lived adversities. Inspired by Martin's call to increase this research, Stinson (2008) wrote about four Black boys and their mathematical success by analyzing the sociocultural and sociohistorical discourses outside the mathematics classroom that affected their agency. Stinson found that the students understood the importance of academic success. Yet, because sociocultural discourses identify African-American men in certain ways, these students were compelled to renegotiate perceived adverse images of them with teachers and community members in order to succeed in the classroom. They responded positively to adverse images either by controlling others' perceptions of them or by not thinking of success as being racialized "the term *nerd* could be applied to all races" (p. 998); they resisted Ogbu's notion of an oppositional culture.

The students also developed a double-consciousness; an awareness and understanding of the positions of both marginalized, excluded populations and hegemonic groups. This positive response proactively avoided violence and minimized the lived adversity. Stinson argued that an individual, whose identity is formed outside the dominant discourse and develops a double-consciousness deliberately or inadvertently, tends to be motivated to be self-empowered or to transform society. By being aware of the hegemonic discourses surrounding Black men, these students understood, and worked to control and alter, others' perceptions of them. They appropriately tailored their behavior in and out of the classroom. Furthermore, the students either rejected or renegotiated Ogbu's ideas on African-Americans' rejection of academic excellence.

These counter-stories contradict theoretical constructs on the failure of African-American boys in mathematics. Two generations after Ogbu's work, Stinson's work looked at positive responses and the success stories of African-American boys to bring the intellectual conversation to a new level. He considered an example, where students are not limited by violence, but are empowered by the positive responses in understanding how society labels them. By controlling the Discourse, these students gained greater control over their destiny. Ogbu's frameworks set the stage for these realizations, since these students found success in both of their worlds by simultaneously accepting and rejecting the lived adversity that comes from both.

Stinson's ideas are illustrated in Jones (2003), which used action research to help a third-grade girl develop a "hybrid identity" in an after-school math club. Similar to the two girls in Lim's work, Patti experienced lived adversity because she enacted two conflicting identities. Her personal, home identity was that of a boisterous, active, African-American girl who was encouraged by her mother to adopt an academic identity (White, middle-class) in school by excelling in mathematics. In contrast, she did not successfully conform to the limited notions of a girl's appropriate behavior in the classroom, which limited her mathematical success. In fact, her teacher did not recognize Patti's mathematical talent and held low expectations for her. Jones used an after-school math club as a third space where Patti and others were encouraged to develop a hybrid identity, a positive response to their lived adversity which included teachers' discouraging remarks. In the club, academic and cultural and personal experiences were valued and encouraged to be part of the discourse, learning was stimulated, and the lived adversity was minimized. Because the math club was a safe space where Patti's identity did not need to be compromised or suppressed, Patti enjoyed mathematics, developed her skills and a strong mathematical identity. Jones' intervention may have prevented results mimicking Lim, showing how the positive response can help a student move away from lived adversity.

Further adding to the success stories of African-American men in mathematics, Berry (2008) documented how a group of Black middle-school boys' mathematics learning experiences' were racialized and how they persisted and succeeded to enroll in Algebra I. Four boys were tested for the academic program at the insistence of their parents or another adult. Their teachers did not recognize the potential and cognitive abilities of these boys; others rejected those notions and advocated on behalf of the child. The parents each believed their child was not considered for the gifted program because of race. These parents did not use what they perceived to be a teacher's racism to develop an oppositional worldview; they did not subscribe to the violence of racism to reify Ogbu's theories. Instead, these parents understood that teachers and principals hold the key to knowledge in the classroom and worked to change their views. The parents developed a positive response to their lived adversity by being involved with school activities to reject any notion that they did not care about their child's academic progress. The parents taught their children that being a Black boy required them to work harder for less recognition, as indicated by the struggle to have school personnel recognize intellectual talents and potential.

As researchers step away from violence to focus on the academic successes of involuntary minorities, they deemphasize violence and consider positive responses. Martin and Jones expand the canon of student experiences from what Ogbu and Lim portray. Stinson conveys a theoretical framework on dual-consciousness, a positive response to one's lived adversities. Berry shows that parents did not develop a segregated worldview that opposes the culture of power; rather based on their lived experiences these parents challenged the hegemonic powers in the schools to respond positively and ensure their children the best education possible.

Beyond Violence: The Positive Response

Ogbu's influence extends to researchers who use his work to frame the positive response. Looking at learning through a cultural lens, Nasir (2002) theorizes how mathematical learning, identity, and goals interact within a community of practice. Nasir, like Martin, builds on Ogbu's framework by suggesting that race and culture influence academics and that identity and learning are connected. Nasir advances Ogbu's theories by supplementing identity and learning with goals. However, rather than emphasize the lived adversity of minority students and their opposition to learning, Nasir portrays minority students as advancing their own learning (albeit in nonacademic contexts) through goal setting and changes in identity.

Nasir examines two practices of African-American culture: dominoes and basketball, and illustrates how mathematics is pervasive and valued in these practices and thus in Black culture. She emphasizes that minority students who are sometimes seen by their teachers as mathematically weak are, in fact, mathematical beings, eager and willing to learn mathematical ideas. Unlike Lim's work (2008), Nasir does not require students to redefine themselves in order to succeed. She does not see sports as a rejection of academics. Instead, she embraces athletics as a way to reach the academic potential of African-American students and places the burden for change upon schools, suggesting that students will excel in learning when learning is well designed. Thus Nasir, while acknowledging and building from Ogbu's work, has, in this article, moved from an emphasis on adversity and violence to a focus on the resiliency of Black youth, showing their celebration of learning in spite of unsuccessful school contexts.

The move toward resiliency is also illustrated in Thompson and Lewis' (2005) case study of a Black high school boy, Malik, in an urban school. Malik's goal was to be a pilot. This motivated him to enroll in upper-level mathematics courses in high school. Such coursework would provide knowledge and strengthen his transcript and applications to competitive colleges. Malik began high school defining success through athletics. Living in a violent neighborhood with high crime rates, drug activity, and low participation in school, Malik witnessed first-hand the detrimental effects of the culture of opposition and rejected it completely. Malik's witnessing of the lived adversity of his community initiated the positive response of setting his personal goal and motivating himself to accomplish this goal in multiple ways, including comparing his academic development with national averages to minimize a false sense of confidence.

Malik's goal redefined his identity as a dedicated student and he consequently petitioned his principal to offer a Pre-Calculus / Calculus course. The principal was hesitant; he felt there was a lack of interest in upper-level mathematics courses. However, he was willing to establish the course if a certain number of students expressed interest. In the end, 16 percent of the graduating students at the school did so, contradicting the notion that African-Americans are not interested in education. This principal did not decide the students' fate, he left it to Malik's agency and the students' motivation, laying the foundation for a positive response and reducing the possibility of contributing to the culture of opposition by denying students their intellectual desires.

Using Ogbu's foundational work, Nasir deemphasizes adversity and develops a framework of positive responses in mathematics learning. Thompson and Lewis illustrate how the lived adversity of the culture of opposition triggered the positive response in a student so strongly that they petitioned and succeeded in having their school offer advanced mathematics classes.

Conclusion

We applied a non-traditional meta-framework to research on mathematics identity and race. This meta-framework starts with violence as a basis for the theoretical constructs that draw from the lived adversities of involuntary minorities. The pervasive experiences that contribute to adversity cannot be ignored when explaining achievements in mathematics. However, they are the beginning and not the ending of frameworks that explore mathematical achievement gaps. These frameworks give way to frameworks that draw upon positive responses. For example, Martin acknowledges that racializing mathematics and recognizing adversity is essential. However, he also contends that race does not have to limit one's mathematical potential. Nasir moves one step further from adversity in her work. She formulates a theoretical positive response based on a lived positive response and celebrates possibility. Her theoretical stance emphasizes strength and power among involuntary minorities while minimizing violence.

Although Nasir and Martin and others do not describe their work in terms of resilience, their acknowledgment of Ogbu's work as a foundation and their work to establish positive theoretical framings suggests that resilience is an appropriate label for the trajectory of their work.

Our meta-framework of resilience suggests that the acknowledgment, proclamation even, of adversity, might be important to the trajectory of research on situations of violence and adversity. It also suggests particular ways in which research that explores lived adversity might develop over time. Finally, it embraces the inspirational call of many nonviolent protestors like Dr. Martin Luther King, Jr.; Nelson Mandela and Mahatma Gandhi who each enacted the belief that injustice could be resolved by first recognizing the multiple kinds of violence and then moving through a positive response toward a more just world.

Endnotes

1. The literature is inconsistent on the use of racial terms and their capitalization. We will use "Black" and "African-American" interchangeably and capitalize all references to race.

STUDENT PERSPECTIVES TOWARD UNDERGRADUATE MATHEMATICS COURSES

Michael D Dornoo
The Ohio State University at Newark
dornoo.1@osu.edu

Lynda R Wiest
University of Nevada, Reno
wiest@unr.edu

This research was an investigation of 208 undergraduate students' perspectives toward undergraduate mathematics instruction. Survey ratings and limited student written commentary were analyzed as a whole and by gender and race/ethnicity. Overall, students tended to report somewhat favorable affect and experiences. However, some students, particularly females, expressed negative perspectives. Participants noted the role of both the instructor and themselves as important factors in defining the undergraduate mathematics experience. The results suggest improvements for undergraduate mathematics instruction.

Purpose of the Study

Most undergraduate students must successfully complete at least one mathematics course to obtain a bachelor's degree (Gupta, Harris, Carrier, & Caron, 2006). Mathematics is important preparation for many fields of study. Mathematics-oriented fields tend to be lucrative, offering workers secure positions that can impact life quality. For example, in 2009 Computer and Mathematical Science Occupations ranked third in mean annual wages ($76,290) out of the U.S. Bureau of Labor Statistics' (2007) 22 major occupational groups.

Nevertheless, many students enter college with insufficient preparation for or poor dispositions toward mathematics courses (e.g., Gupta et al., 2006; Schmidt, 2007). They may fail to see the utility of the subject. They may avoid mathematics coursework beyond that which is required and even avoid careers with substantial mathematics demands. Some research findings associate attitudes and beliefs with mathematics performance and participation (e.g., Watt, Eccles, & Durik, 2006). Perspectives on mathematics may differ by students' "social identities," such as gender and race/ethnicity. For this reason, some researchers (e.g., Lubienski, 2008) encourage mathematics education researchers to study gaps among different student groups as a springboard from which to launch equity efforts. More research is needed to examine the undergraduate mathematics experience as a starting point for improving undergraduate mathematics courses. Accordingly, the survey research reported here investigated 208 undergraduate students' perspectives toward undergraduate mathematics instruction. The data were analyzed as a whole and by race/ethnicity and gender.

Theoretical Framework

The following topics related to undergraduate mathematics learning are discussed briefly below: occupational importance of mathematics, mathematics anxiety, instructional strategies and mathematics performance, and the relationship of race/ethnicity and gender to mathematics.

Occupational Importance of Mathematics

Many jobs call for mathematics skills, as does daily life itself (e.g., Bureau of Labor Statistics, 2007; Stubblefield, 2006). According to Bureau of Labor Statistics (2007) projections, many jobs that once required little mathematics background will call for specific skills in algebra, geometry, measurement, probability, and statistics. Prevot (2006) found that many fields, such as economics, commerce, and medicine, are taking on mathematical aspects, so that individuals unfamiliar with algebraic symbolism and higher mathematics may struggle to read some of the current literature in these fields. Goodman and Stampflii (2001) report that many employers prefer mathematically trained candidates for secretarial and administrative assistants, especially where statistical or accounting work may be required. They also note that life insurance companies and industrial research organizations provide numerous positions for mathematicians.

Mathematics Anxiety

Most students resist taking mathematics courses due to anxiety toward the subject. This anxiety is so strong that many students defer taking mathematics courses until their last semester of undergraduate studies (Liljedahl, 2005). Tobias and Weissbrod (1980) define mathematics anxiety as the panic, helplessness, paralysis, and mental disorganization that arise in some people when they are required to solve a mathematical problem. Mathematics anxiety, a common phenomenon among college students, exceeds a dislike of mathematics (Perry, 2004; Vinson, 2001). Many researchers have documented that mathematics anxiety stems from students' fear of failure and feeling of inadequacy. In particular, Krantz (1999) describes this extreme form of mathematics anxiety as the inability by an otherwise intelligent person to cope with quantifications and, more generally, mathematics. If students suffer from mathematics anxiety, their willingness to enroll and succeed in mathematics courses is diminished (Stubblefield, 2006). Consequently, many students at the undergraduate level tend to view mathematics with negative attitudes and feelings, which have been found to explain a significant portion of the variance in student learning (Gupta et al., 2006; Papanastasiou, 2003). Students who do well in mathematics have more positive attitudes about the subject; they are thus likely to take more courses and may perform better (Tapia & Marsh, 2004). However, many students enter undergraduate programs with an already developed attitude toward mathematics instruction (Gupta et al., 2006).

Instructional Strategies and Mathematics Performance

An instructor's method of teaching can impact students' attitudes toward mathematics. According to Walczyk and Ramsey (2003), students complain that instruction that is primarily lecture is boring and hard to relate to, grading does not reflect achievement, competitive rather than cooperative learning is emphasized, memorization receives greater focus than understanding, concepts are not linked, demonstrations are rarely used, little class interaction takes place, and faculty are indifferent. On the other hand, students report that good teaching practice consists of consciously constructing a supportive learning environment that can increase students' interest and success in mathematics and show students various ways to approach the same mathematics problem (Carlan, 2001).

The Relationship of Race/Ethnicity and Gender to Mathematics

Mathematics performance and attitudes have been found to differ by race/ethnicity and gender, thus making these demographic factors important to consider in conducting research (e.g., Acherman-Chor, Aladro, & Gupta, 2003; Ma, 2006). These "social identities" intersect in ways that further complicate simple data interpretation (Riegle-Crumb, 2006). Tapia and Marsh (2004) posit that among college students, feelings about mathematics mainly relate to individual personal experiences. Ma's (2006) research found that racial/ethnic differences in mathematics were more evident among students from socially advantaged than from socially disadvantaged backgrounds. For example, Hispanic students from socially advantaged families failed to do well in mathematics courses. Thus, Ma (2006) cautions that a family's socioeconomic background may not predict participation and success in mathematics course work; rather, "It actually depends on the racial-ethnic background of students" (p. 145).

In their research on a cohort of college algebra students, Acherman-Chor, Aladro, and Gupta (2003) found that ethnic minorities received more encouragement and motivation from their parents than White students. In terms of role models, African American teachers can help shape how African American students perceive themselves as learners and doers of mathematics, as well as stimulate a sense of belonging in the mathematics classroom and eventually in the field of mathematics (Moody, 2004). Acherman-Chor, Aladro, and Gupta (2003) found, "Contrary to the established assumption that minority parents do not understand the value of higher education, both Hispanic and Black students reported higher levels of parental educational expectations than did their White counterparts" (p. 141).

Most students, in general, tend to have positive attitudes about the pursuit of mathematics when they feel inspired and determined to succeed (Liljedahl, 2005; Tapia & Marsh, 2004). Although women exhibit high levels of math anxiety, they perform well in relation to men in college mathematics (Acherman-Chor et al., 2003; Van Nelson & Leganza, 2006). As noted, Tapia and Marsh (2004) posit that among college students, feeling good about mathematics relates to individual personal experiences more than the social construct of gender.

Methodology

Participants and Data Collection

The study included 208 undergraduate students enrolled in mathematics courses at a large western U.S. public university during the spring semester of 2007. Participants whose instructors consented to participate in the study were enrolled in Intermediate Algebra, Number Concepts for Elementary School Teachers, Precalculus and Trigonometry, Calculus I, Calculus II, or Calculus III. The participants, who ranged from freshmen to seniors, consisted of 99 females (47.6%) and 106 males (51.0%) from 11 undergraduate mathematics classes. (Three students' gender, accounting for the remaining 1.4%, was not disclosed,) Of the 208 participants, 1.9% were American Indian or Alaskan Native, 1.9% Black, not of Hispanic origin, 8.2% Hispanic, 9.1% Asian, Native Hawaiian, or Pacific Islander, 73.1% White, not of Hispanic origin, 3.4% other, and 2.4% racially undisclosed.

The research was a quantitative study based on survey-item ratings that were supported by limited qualitative data in the form of written comments. Students' written comments helped the researchers interpret the ratings. The quantitative and qualitative data were collected at the same time and were both considered integral to the data analysis. According to Hanson, Creswell, Plano-Clark, Petska, and Creswell (2005), "Using both forms of data allows researchers to simultaneously generalize results from a sample to a population and to gain a deeper understanding of the phenomena of interest" (p. 224).

A 29-item, author-developed questionnaire was used to assess participants' perspectives toward undergraduate mathematics. Items were based on undergraduate students' experiences with and perspectives toward mathematics, as gleaned from the professional literature and the authors' professional experiences as college instructors in mathematics and mathematics education. Questions addressed such areas as perceptions of the difficulty level of mathematics and expectations for students' performance in mathematics. Participants responded to the first 28 items on a five-point Likert scale with choices of "strongly disagree," "disagree," "unsure," "agree," or "strongly agree" for each statement. Participants had the option to provide comments after each of the 28 items to explain their ratings. The final item was an open-ended invitation to provide any other comments participants might want to make. The survey was administered to ten of the eleven classes at the beginning of class and one at the end of class.

Data Analysis

Survey ratings were assigned scores ranging from 1 for "strongly disagree" to 5 for "strongly agree." These quantitative data were analyzed using SPSS statistical software. Descriptive statistics were figured for the data as a whole and the data disaggregated by gender and race/ethnicity. The number of participants in each racial/ethnic minority group—American Native or Alaskan Native; Black, not of Hispanic origin; Hispanic; Asian and Native Hawaiian or Pacific Islander—were small compared to White participants, so race/ethnicity was put into two groups, non-White (n = 51; 24.5%) and White (n = 152; 73.1%), for the purpose of data analysis. A Mann-Whitney test was used to compare mean scores for survey items by gender and race/ethnicity with an alpha level of .05 established for determining significance.

Student written comments were analyzed by performing multiple readings of the data to construct conceptual categories that appeared to reflect participant perspectives (cf. Bogdan & Biklen, 2007). The authors repeatedly coded student comments separately and together until they agreed on the coding categories used, classification of student comments, and general themes observed. Written commentary was analyzed as a whole and separately by gender and race/ethnicity.

Findings

Quantitative Analysis

The ten most extreme mean ratings, those farthest from a rating of "unsure" (3.0), are weighted more heavily toward positive portrayals of the undergraduate mathematics classroom, as shown below. (Scores above 3 tend toward "agree" and those below 3 toward "disagree.") One possible exception is the tendency to perceive classroom instruction as mainly lecture, if presumed that lecture is construed as an undesirable method (which does appear to be the case based on some written comments). However, as worded, the item is descriptive rather than evaluative.

- I believe that I am capable of doing well in mathematics (4.1).
- I am provided with challenging, thought-provoking problems in math class. (4.0)
- Tutoring or other help outside of math class would help me improve my math performance. (3.9)
- My math instructors encourage me to do my best in mathematics. (3.9)
- I am encouraged to ask questions in math class. (3.8)
- The main teaching method for my math classes is lecture. (3.8)
- My math instructors hold high expectations for my performance. (3.7)
- My math instructors give me extra time and assistance in and out of class when I need it. (3.7)
- Some students are expected to do better in mathematics based on their race/ethnicity and/or gender. (2.3)
- Classmates often intimidate me in math class. (2.3)

Ratings for some items tended toward more negative positions but not as strongly as the more positive perspectives indicated above. The most salient is, "Mathematics is a difficult subject area" (3.5). Gender differences, and to a much lesser degree race/ethnicity, are evident. Significant differences according to these participant subgroups are shown below. Effect sizes also appear in parentheses, with the magnitude characterized as small (.01), medium (.06), or large (.14).

Gender. Males assumed a more favorable score for each rated comment below. In most cases, both mean scores tended to be favorable or unfavorable but were nevertheless significantly discrepant.

- I fear mathematics. ($p < .001$; .66, large effect)
- I feel fear/anxiety when taking mathematics tests. ($p < .001$; .67, large effect)
- Instructors often intimidate me in math class. ($p < .01$; .04, medium effect)
- Classmates often intimidate me in math class. ($p < .001$; .055, medium effect)
- Mathematics is taught in a way that matches the way I think and learn. ($p < .01$; .04, medium effect)
- I would like to take more math courses than what is required for my major. ($p < .01$; .04, medium effect)
- I believe that I am capable of doing well in mathematics. ($p < .05$; .02, small effect)
- My parent(s) hold high expectations for my math performance. ($p < .05$; .02, small effect)
- My parents have actively encouraged me in mathematics (e.g., said I was good at it or encouraged me to take more/higher math). ($p < .05$; .02, small effect)

Race/Ethnicity. White students rated the first two items below significantly more favorably than non-White students. Non-Whites rated the final two comments more strongly. These four differences have small effect sizes.

- I believe that I am capable of doing well in mathematics. ($p < .05$; .02, small effect)
- Classmates often intimidate me in math class. ($p < .05$; .02, small effect)
- Tutoring or other help outside of math class would help me improve my math performance. ($p < .05$; .02, small effect)
- Mathematics is taught in a way that matches the way I think and learn. ($p < .05$; .02, small effect; .02, small effect)

Qualitative Analysis

One-fourth of the sample (52 students) provided a written response to the final, open-ended response: “Please add any other comments you would like to make.” Despite the influence of gender, and to a lesser degree race/ethnicity, noted above, written comments indicated that students’ perspectives on mathematics also bear a strong association with individual personal experiences apart from demographic characteristics. Individual experiences include, for example, presence or absence of strong role models, parental or self-expectations for performance, and personal work ethic. Three dominant themes, each described briefly below, appeared across students’ written comments: the role of mathematics or test type, instructional factors, and student preparation and effort.

Mathematics/test type. As noted earlier, the survey ratings show that students tend to believe they can do mathematics despite a somewhat lesser tendency to find mathematics difficult. Written comments indicate that these perceptions depend, however, on the type of mathematics and mathematics problem or exam given. Typical student responses were, “I have trouble with Integral Calculus more than any other kind of math,” “It can be really easy and it can be extremely difficult, often depends on the question,” and “It depends. I do better in some math topics than others.”

Instructional factors. In general, students credited instructors with a strong role in the undergraduate mathematics experience. Many claimed that the difficulty level depends on the instructor. For example, one said, "If teacher is good it can be easy" and another the opposite: "Some teachers make it harder than it really is." Students expressed a desire for good, comprehensible explanations that include examples and meaningful applications. They indicated that they want a slower instructional pace and greater engagement. Several students suggested smaller class sizes through comments such as the following:

- I strongly believe math classes should have way less students. The classes are too big and the instructor can't engage with everyone and answer every single question.
- Smaller class sizes are much more effective in teaching because students will actually ask questions. It's intimidating to ask a question in a large lecture hall.

Student preparation and effort. In their commentary, participants tended to acknowledge their own responsibility in exerting effort and investing sufficient time to be properly prepared for and successful in their mathematics classes. They made such comments as, "Math is not difficult if you attend class," "It only depends on how much work and effort you are willing to put in," and "I can do anything… I'm just lazy." In accepting the relationship of their work effort to performance and evaluation outcomes, several students described associated stress and time constraints, as the following comments illustrate:

- I have to work really hard, and it's really stressful.
- Math takes a lot of time and self-discipline, if given the time I think I can do well.
- I would have to spend time I don't have to do better.

Student effort also includes seeking help outside of class. As gleaned from students' written comments, the three most common sources where students attained help were, in order, the university mathematics center (which provided tutoring), peers/friends, and course instructors. Some students contend that they can perform well if the instructor provides extra help outside of class or they seek tutoring. Females reported a slightly greater tendency than males to need or seek mathematics help outside of class, especially through structured academic services such as tutoring and mathematics centers.

Significant differences by student subgroups. Student comments support ratings that portray a somewhat less positive experience for females than males in mathematics. For example, females made seven of the nine negative comments displaying negative attitudes or beliefs in relation to survey item "I fear mathematics". They wrote statements such as "I am just not good at math." and "I go in knowing I [am] not going to do well." Likewise, for the item "My parent(s) hold high expectations of my math performance," females provided all three written responses that indicated a lack of high parental expectation for their mathematics performance, for example: "They understand that it's not a strength of mine." In reference to whether they would take more mathematics courses than required for their major, females tended to make much stronger assertions. Two said, "No way!" Others said, "No more than necessary please!," "No thank you," and "Once my major requirements are fulfilled…I am done with math. Period." Male students' comments were much less dramatic, often indicating that they might take more mathematics and sometimes suggesting practical reasons for not pursuing more, such as "Would like to, but major requirements don't leave room for extra coursework" and "I would love to learn more, but…pure math will only hurt my GPA." No prominent differences by student race/ethnicity are evident in the written commentary.

Limitations

A minor limitation of this study is that one class completed the survey at the end of class, whereas the others were completed at the beginning of class. It is possible that students in this class spent less time and conceivably less thoughtfulness in providing survey responses. Another limitation is that race/ethnicity was divided into two categories for the purpose of analysis. Although this categorization is convenient for analysis and bears merit in the general sense that White students are presumed to have greater privilege than students of color on the whole, important distinctions among racial/ethnic groups are ignored in this type of classification. Further, the subsample size for non-White students was somewhat small. Finally, performing multiple Mann-Whitney comparisons increases risk of Type I error and thus interpretations must be considered tentative.

Closing Discussion

Somewhat contrary to what one might presume based on research regarding students' mathematics anxiety, this sample's strongest ratings tended to be somewhat favorable in relation to the undergraduate mathematics experience, although this varied by type of mathematics and instruction. Nevertheless, a sufficient number of students, in particular, females, report unpleasant experiences in the subject, calling for continued efforts to improve undergraduate mathematics instruction. The method of delivering instruction as it relates to such factors as the instructor's role and class size appeared to be the most important component in crafting classroom climate. A number of students suggested, for example, a slower pace of instruction. Within our math-phobic society, this is something we can control and should give due consideration. One female urged, "This study should be seriously considered."

The results of this study indicate that gender is still an important issue in mathematics instruction. Regardless of student achievement levels, student dispositions continue to matter in a number of ways, such as their potential impact on future course and career participation. In addition to showing less favorable attitudes and beliefs than males, females reported less parental support. This resonates with other research that females are significantly less likely than boys to receive maternal encouragement to participate in out-of-school STEM (science, technology, engineering, and mathematics) activities or parental provision of activity-related materials (Jacobs & Bleeker, 2004; Simpkins, Davis-Kean, & Eccles, 2005). This points to the continued importance of educating parents and the public at large of the value of mathematics for *all* students.

Gender appeared as a greater concern in these study results than race/ethnicity. Nevertheless, racial/ethnic minorities were less likely than Whites to believe in their mathematics abilities and were more susceptible to classmate intimidation, although they tended not to experience such intimidation in general. It is not surprising that females were less likely than males to rate mathematics instruction as matching the way they think and learn, but it seems unusual that students of color found classroom instruction a better match for them than Whites. This small effect may be real or a product of a relatively small subsample size and the fact that all racial/ethnic minority groups were combined into one group for statistical comparison, blurring distinctions among groups. Nevertheless, this finding would be worthy of further study.

It is encouraging that many students seemed to recognize the importance of their own effort and preparation. In addition to an externalized focus on instructional methods, this means that students also accept a substantial amount of responsibility for their own learning and view their degree of success as something they can influence, an important belief. Some students expressed frustration with a lack of time to sufficiently apply this work ethic. This returns to the idea of the fast pace of instruction that may hinder understanding and foster hopelessness in students. In conclusion, it seems that undergraduate mathematics instruction would benefit from a balanced approach of improving mathematics instruction (e.g., using a slower and more conceptual approach), seeking to influence high societal expectations for all students in mathematics, and reinforcing students' understanding of the importance of personal effort in learning mathematics, which includes seeking available outside resources.

MRS. THOMAS: A CASE CONCEPTUALIZING A TEACHER'S KNOWLEDGE OF EQUITY IN TEACHING MATHEMATICS

Christa Jackson
University of Kentucky
christa.jackson@uky.edu

Mathematics educators constantly discuss equity in the classroom, but do we know what equity in mathematics looks like? Establishing an equitable classroom environment that results in student learning for African Americans requires specialized teacher knowledge, productive dispositions and beliefs, and effective teaching practices. In this case study, I use the Knowledge of Equity in Teaching Framework to unpack a successful elementary mathematics teacher's knowledge of equity in teaching mathematics to African American students. The results of the study reveal the components of the framework influence each other.

W. E. B. Du Bois, one of the founders of The National Association for the Advancement of Colored People (NAACP), envisioned that the education of African Americans would equip leaders to protect the political and social rights of the Black community. Realizing Du Bois' vision requires more effective teacher education as well as support structures for teachers. Unfortunately, the majority of teachers are not fully equipped to educate a diverse population of students. Currently, in the best of circumstances we have mathematics teachers who have strong mathematical content knowledge and high levels of pedagogical content knowledge, yet African American students are still underperforming in mathematics (Martin, 2009).

Research has described different knowledge bases required for teaching including knowledge of mathematics content that relates directly to the mathematics they teach, typical student errors and misconceptions and how to deal with them, and how to work in diverse school settings, including an understanding of the conditions of their students' lives and of the social factors that affect schooling (Ball, Hill, & Bass, 2005; Ma, 1999; Shulman, 1986). Yet, no research has involved understanding teacher knowledge related to equity in teaching mathematics to African American students.

The purpose of this case study is to understand an elementary teacher's knowledge as it relates to equity in the instruction of mathematics to African American students. The research questions underlying this study are:

1. What knowledge related to equity in teaching African American students does a successful elementary mathematics teacher draw upon?
2. What beliefs related to teaching mathematics to African American students influence the mathematics teaching of a successful elementary mathematics teacher?

Conceptual Framework

Teachers must develop and draw from numerous knowledge bases to effectively teach mathematics to all students. Although mathematics education researchers have studied knowledge for teaching over the past two decades (e.g., Carpenter, Fennema, Peterson, & Carey, 1988; Hill, Ball, and Schilling, 2008; Hill, Rowan, & Ball, 2005; Ma, 1999), the conceptualization and research related to the knowledge of equity has not been pursued. As a result, I developed a conceptual framework related to teachers' knowledge of equity issues, beliefs, and teacher's knowledge of equity pedagogy based on a review of the literature (see Figure 1).

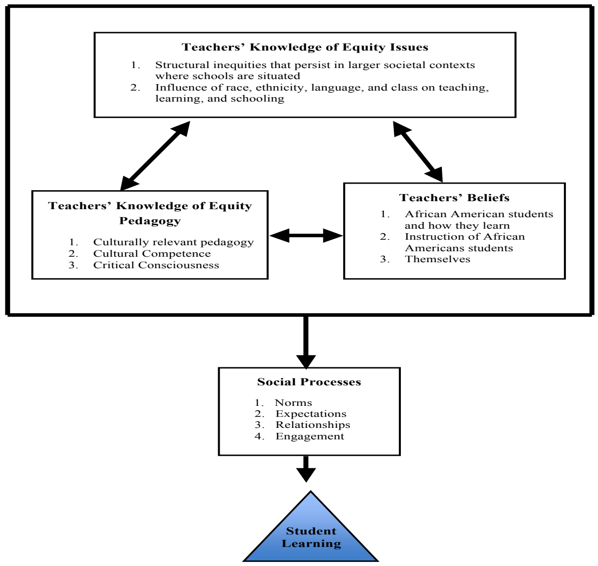

Figure 1. Knowledge of equity in teaching framework.

The top section of the framework emphasizes that teachers should develop knowledge about structural inequities that persist in larger societal contexts where schools are situated as well as the influence of race, ethnicity, language and class has on teaching and learning. Pai (1990) suggests:

> Our goals, how we teach, what we teach, how we relate to children and each other are rooted in the norms of our culture…In a society with as much sociocultural and racial diversity as the United States, the lack of this wonderment about alternative ways often results in unequal education and social injustice. (p. 229 as cited in Gay, 2000, p. 23)

The rectangle on the right side of the framework emphasizes teachers' beliefs. Philipp (2007) asserts beliefs are "psychologically held understandings, premises, or propositions about the world that are thought to be true…beliefs might be thought of as lenses that affect one's view of some aspect of the world or as dispositions toward action" (p. 259). Teachers need productive beliefs specifically related to African American students, how African American students learn, and effective teaching practices for African American students. Moreover, they need productive beliefs related to themselves as teachers and the roles they play as they teach mathematics through an equitable lens.

On the left-hand side of the conceptual framework, I include three components within knowledge of equity pedagogy: culturally relevant teaching, cultural competence, and critical consciousness. Ladson-Billings (1994) defines culturally relevant teaching as a "pedagogy that empowers students intellectually, socially, emotionally, and politically by using cultural referents to impart knowledge, skills, and attitudes" (p. 17). Gay (2000) extends this definition by stating culturally responsive teaching is "using the culture knowledge, prior experiences, frames of reference, and performance styles of ethnically diverse students to make learning outcomes more relevant and effective for them" (p. 29). Culturally relevant teaching is designed to teach the "whole" child through acknowledging and addressing the child's race, language, ethnicity, and class through teaching. Students' "identities" are not ignored or subsumed in the deficit model of teaching and learning, but are contributors to the teaching and learning of students. For example, culturally relevant teachers use the strengths, experiences, and accomplishments of students in their instructional approaches.

Cultural competence includes teachers' knowledge about their own culture and the role it has in their lives; knowledge of students' cultures; the necessity to *study their students* (Ladson-Billings, 2001); and the ability to communicate (both verbal and nonverbal), understand, and interact with people from different cultures. A culturally competent teacher has the capacity to function in other cultural contexts.

Critical consciousness engages both teachers and students to critically question, reflect, participate in meaning making, and act in their sociopolitical environment. Ladson-Billings (2001) suggests teachers who promote critical consciousness: (a) have knowledge of the larger sociopolitical context; (b) invest in students and understand students are important for who they are and who they can become; (c) plan and implement academic experiences that connect students to the larger social context; and (d) believe the success of students has consequences for their quality of life.

The conceptual framework outlines the critical components of knowledge of equity issues, beliefs, and knowledge of equity pedagogy. It guided the design and implementation of a larger study (see Jackson, 2010). In this article, I report the findings of the three components of the framework for one teacher.

Methods

Participants

Participants were identified based on the following criteria: (1) Teach mathematics in grades 3-5; (2) Composition of mathematics class is at least 20% African American students; (3) Have a minimum of 4 years of teaching experience; (4) Recommended by knowledgeable mathematics educators based on competence in teaching African American students; and (5) Recommended based on mathematics achievement of African American students on state and/or local assessments.

I contacted the Hartville School District's Superintendent (all names are pseudonyms) who placed me in contact with the mathematics coordinator. The mathematics coordinator identified seven teachers whose African American students had high average achievement scores on the district assessment (75% and above). She also confirmed with the building principals that these teachers have a positive rapport with their African American students. Through their recommendations, Mrs. Thomas was asked, and agreed to participate.

Data Collection

The data sources included semi-structured initial and final interviews to determine Mrs. Thomas' knowledge related to equity in teaching mathematics to African American students. Each interview lasted approximately one hour. In addition, I observed and videorecorded her teach eight mathematics lessons during the months of November-January. I wrote field notes during each observation and then followed up with four unstructured stimulated-recall interviews, which lasted 35-50 minutes each.

Data Analysis

After conducting audio-recorded interviews, I transcribed the data. The transcripts were then uploaded into QSR NVivo 8 software and coded using a microanalysis with nodes related to the Equity in Teaching Framework. I used the coding categories shown in Table 1. After the initial coding, other themes emerged. I then conducted a second layer of coding with these emerging themes. Two doctoral students each coded an interview transcript using the coding dictionary.

All discrepancies were resolved and clarified. Finally, I mapped out Mrs. Thomas' knowledge of equity. Reliability was confirmed with another faculty member.

Table 1

Coding categories for teachers' knowledge of equity in teaching

Teachers' Knowledge of Equity	• knowledge about structural inequities that persist in larger societal contexts where schools are situated • knowledge related the influence of race, ethnicity, language and class on teaching and learning
Teachers' Beliefs	• productive beliefs specifically related to African American students • how African American students learn • effective teaching practices for African American students • productive beliefs related to themselves as teachers and the roles they play as they teach mathematics

Teachers' Knowledge of Equity Pedagogy	• Culturally relevant pedagogy
	  • view themselves as part of a community
	  • help students to make connections between their racial, cultural, local, national, and global identities
	  • establish relationships with students that extend beyond the classroom environment
	  • establish a community of learners
	  • believe knowledge is constantly recycled, re-created, and shared by students and themselves – it is not static
	  • view teaching as students developing their knowledge
	  • use a variety of instructional strategies
	• Cultural competence
	  • knowledge about their own culture and the role it has in their lives
	  • knowledge of students' cultures
	  • understand the necessity to *study their students*
	  • ability to communicate (both verbal and nonverbal), understand, and interact with people from different cultures.
	• Critical consciousness
	  • knowledge of the larger sociopolitical context (i.e., knowledge of political and social realities in which they live beyond the television and newspaper articles)
	  • invest in students and understand students are important for who they are and who they can become
	  • plan and implement academic experiences that connect students to the larger social context
	  • believe the success of students has consequences for their quality of life

Results

Mrs. Thomas, an African American woman, began her teaching career 13 years ago at a school in the eastern section of the United States. After her husband received a job transfer, she accepted a position as an elementary teacher in a suburban district in the Midwest. During the past four years, Mrs. Thomas has taught third grade at the same school within this district. Currently, this school reports a student population that is 30.1% African American.

Mrs. Thomas' Knowledge of Equity Issues

Mrs. Thomas believes many teachers of African American students do not understand their culture and misinterpret their actions. As a result, they are essentially penalized for their African American identities. Mrs. Thomas explains:

> When we're teaching African American students, a lot of times we punish African American students for behaviors that they've been conditioned to. A student who goes to the principal's office for shouting out in class for disruptive behavior when the student was participating, the student was disrespectful or because the student was shouting out and the teacher had rules. And one of the things was we had to reconsider our rules based on the needs of the students. So, it's like you can't make students conform to a society when it's something that they're doing in their own home. And it's something that is considered normal, or when they go to a church it's considered normal. We're not saying that it's the way to function, but it's a way of understanding. (Stim-recall 1, 2009)

A statement like this suggests that Mrs. Thomas believes that teachers, white or black, are indoctrinated to filter students' actions through Eurocentric culture and beliefs. This culture dictates what is valued and how students need to behave and respond in a classroom setting. She works hard to try to help her white colleagues realize they need to understand African American culture and build relationships with students. Mrs. Thomas expresses,

> A [white] teacher thinks, well if I pay more attention to this student is because it's the

> white guilt. And so, I think they are missing the mark. Like I don't think they understand. They think well, I don't want to give special treatment to African American students. And it's not special treatment, it's just understanding differences. I mean I can't help it. There are differences. (Final Interview, 2010)

This quote illustrates that Mrs. Thomas believes white teachers feel they need to treat all of their students the same. However, she knows that equal treatment is not possible. Teachers need to acknowledge and understand there are differences and use those differences to support and build students' mathematical knowledge.

Mrs. Thomas' Beliefs and Knowledge of Equity Pedagogy

Mrs. Thomas believes effective mathematics teachers of African American students understand why individual African American students act in certain ways, and learns these aspects when he/she builds and establishes relationships with students. Mrs. Thomas explains:

> We don't want to stereotype them and say oh well since African American students are like this, I will teach like that because sometimes they don't fit a stereotype. There really isn't a stereotype. It's just that sometimes culturally in a household you know you just respond to things differently. Some students may talk in an aggressive way, but an aggressive way is joking. And if you don't understand that then you are always making that student have some kind of consequence. So, I think just understanding students culturally, where they're coming from, and when students do certain things it may not be an aggressive behavior, it's just who they are. If you pretty much have that relationship with that student and understand who those students are, then I think you'll be an effective teacher. (Final Interview, 2010)

Once Mrs. Thomas establishes relationships with her students, Mrs. Thomas contends her students cooperate because they trust her. They feel they can relate to her. She knows the students feel comfortable with her when they begin to call her "Mommy" (Final Interview, 2010). She believes her identity and cultural background allows her to make mathematics relevant. She clarifies, "If we go back to me being an African American, when I present something they think it's relevant because I'm doing it. They can trust me. I have that face that's familiar to them" (Final Interview, 2010).

Mrs. Thomas believes mathematics lessons must be relevant and African American students learn mathematics best when they solve mathematics problems that are related to their life experiences. As a result, Mrs. Thomas creates mathematics lessons using stories that her students share with her. For example, one of her students talked about a trip he made to the store to purchase an item. She had the class pretend they were going to the store to purchase a pack of gum and then posed problems about the amount of change the cashier returned. Mrs. Thomas finds that when she relates mathematics to real life experiences, her students are more successful. Further, Mrs. Thomas believes when she relates mathematics to something the students enjoy this connection enhances their mathematical knowledge. For example, one of her male students likes to dance. Mrs. Thomas used the context of the number of beats he used while dancing to help him build understanding for multiplication. Multiplication finally made sense.

Furthermore, Mrs. Thomas believes her African American students are visual and tactile learners. Mrs. Thomas believes her non-African American students also learn in a similar manner, yet she contends that her African American students have "unique learning styles" (Final Interview, 2010). She describes a student who constantly hears music when none is playing, and he likes to move. Mrs. Thomas realizes that if this boy is seated while she explains a mathematical concept, she loses him. To accommodate his learning culture, she incorporates movement during her mathematics lessons. She describes, “I try to incorporate having kids move around, do a lot of clapping, or do something with rhythms. I think that African American students, they participate more. They say, ‘ooh this is fun.’ They don’t say, ‘this is boring’” (Initial Interview, 2009). Mrs. Thomas believes all of her students benefit from movement, clapping, and rhythms, not just her African American students. Mrs. Thomas remarks, “I do pay attention to how they’re learning” (Initial Interview, 2009), and she believes it is imperative that she integrates ideas into her daily plans that will facilitate learning.

Mrs. Thomas uses a variety of instructional strategies to help her students develop their mathematical knowledge. She understands the African American culture and adapts her instruction to meet their needs. She explains:

> When you’re teaching students, especially students in the African American community, they like to shout out answers. Instead of penalizing them for shouting out answers, make it part of your lesson. So there are times when shouting out is okay. And I let them know that they don’t have to sit and wait on me to call you out or wait for a spinner. Sometime they just have to get it out…So I give them the opportunity to shout it out. (Stim-recall 1, 2009)

Mrs. Thomas recognizes this strategy is also effective with her non-African American students. She comments, “They love it” (Stim-recall 1, 2009). Further, Mrs. Thomas engages African American students by capitalizing on their cultural identity. She understands that part of the African American culture is participating in a call and response environment. Therefore, she creates informal dialogues during her mathematics lessons. These instructional strategies facilitate the participation of Mrs. Thomas’ African American students. Mrs. Thomas remarks, “Sometimes, unfortunately, you can’t get the students to learn the way that you want them to learn, but you have to find a way to make them successful (Final Interview, 2010). Mrs. Thomas understands that when she builds on her students’ strengths and makes the mathematical content relevant, her students are successful.

In Mrs. Thomas’ classroom, everyone must discuss his or her mathematical strategies. They cannot simply say, “Oh I did the problem, here it is.” They must explain their strategies to their peers and make sure their peers understand. In other words, students assume the role of the teacher. This instructional approach not only gives students ownership in developing their mathematical knowledge, it also deepens their mathematical understanding.

Mrs. Thomas believes that African American students must be active in the mathematics classroom. She thinks they should play mathematical games, discuss what they learn, and participate in hands-on activities and math workshops. Teachers need to instruct students by building conceptual understanding of mathematical concepts. Mrs. Thomas asserts:

> Kids become robotic with math. And they will say okay, you add the 6 plus 2 then you add this and then you put it together, but they don’t understand what it means. And so they have to talk while they’re doing it. So, they are talking about it, doing it to go with what they’re saying, and incorporating the vocabulary words. And they put all of that together they learn their best. (Initial Interview, 2009)

Mrs. Thomas does not want students to experience frustration or say that mathematics is hard because they have to solve a problem one particular way. She believes this is one of the reasons why there is an achievement gap in mathematics between African American students and other ethnicities. Consequently, Mrs. Thomas encourages students to use a variety of strategies to solve mathematics problems. She recalled a time when one of her African American students struggled to solve subtraction problems. He began to use a number line and counted up to solve subtraction problems. This approach worked for him and he was able to get the correct answer. Mrs. Thomas wants her students to understand there are many different ways to solve mathematics problems. When she gives her students a multiplication problem, some of them use their fact knowledge, some draw pictures, while others use repeated addition. They all end up with the same result although they use different strategies. Mrs. Thomas adds, “That’s what I love about it, the possibilities. It’s something I can always apply.” (Final Interview, 2010).

Moreover, Mrs. Thomas realizes all of her students are not *A* students, yet she understands that her students do not leave her class with the same knowledge they came in with. She wants her students to pass third grade so they can move to 4th grade, yet she desires more for her students. She explains:

> I think about where they’ll be 20 years from now. How will they compete in this type of economy? You can graduate from high school learning the basics, but not the higher level thinking, like matrices, calculus to get you into the 21st century…We have to get into what is beyond mathematics number sense. You know, why numbers are a certain way, why it makes sense, and always finding a way to incorporate it with real life experiences. That’s the big thing. So, I look at my kids, I want them to be able to do well in 10 years and give them all the skills that they need. (Initial Interview, 2009)

Above all, Mrs. Thomas aspires to equip her students with the mathematical knowledge they need to successfully compete in today’s society.

Discussion

Mrs. Thomas’ Knowledge of Equity in Teaching

Mrs. Thomas’ knowledge of equity in teaching focuses on knowledge that teachers, both black and white, are indoctrinated to structure the mathematics classroom and filter African American students actions through Eurocentric culture and beliefs. But, Mrs. Thomas uses the cultural capital of her African American students to help them become successful in the mathematics classroom. As a successful mathematics teacher of African American students, she believes she understands why African American students act in certain ways. Thus, in her pedagogy she positively incorporates those “actions,” which are manifested in her social processes. In this context, Figure 2 represents how Mrs. Thomas’ social processes are influenced by the interconnection among her knowledge of equity issues, beliefs and knowledge of equity pedagogy.

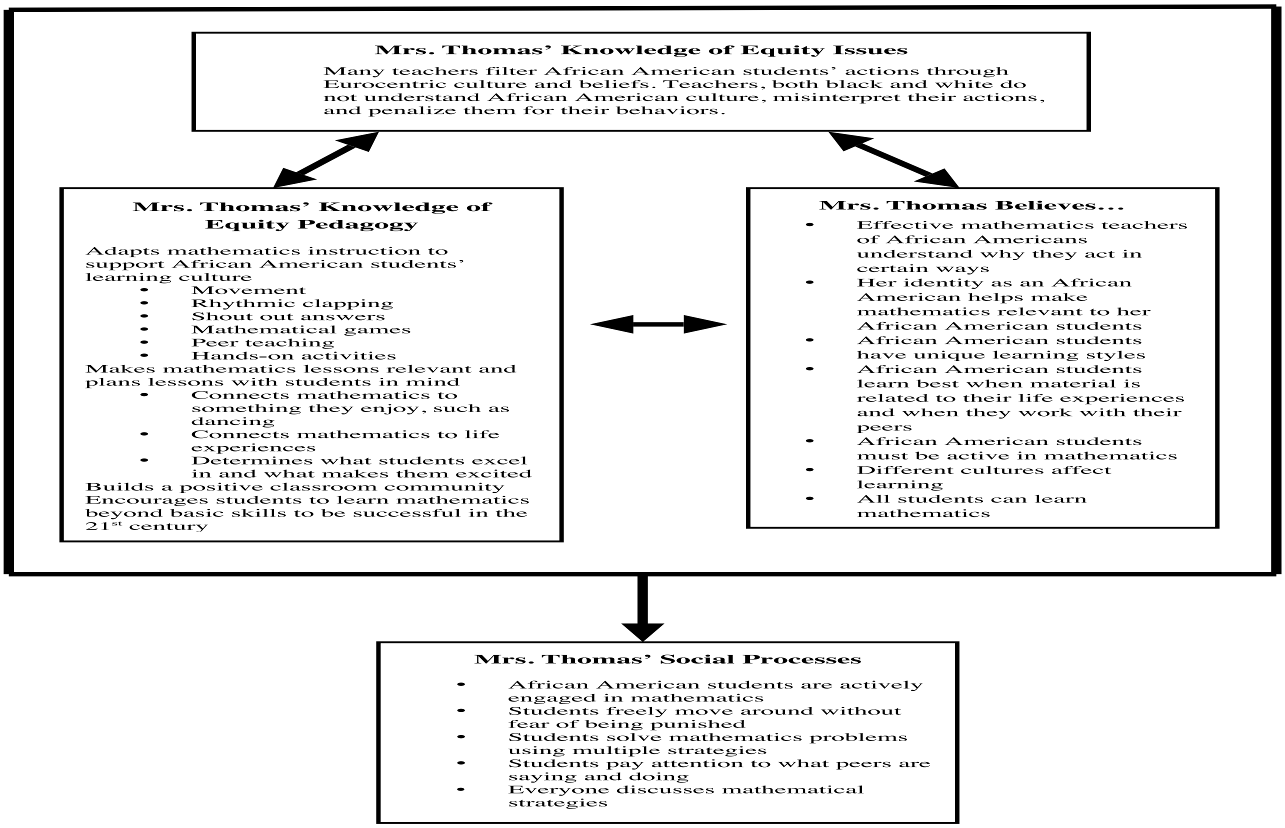

Figure 2. Mrs. Thomas' knowledge of equity in teaching.

Conclusion

The underlying theme of the Equity Principle in the *Principles and Standards for School Mathematics* (NCTM, 2000) is all students can learn mathematics. Unfortunately, many African American students are consistently demonstrating low mathematical achievement. Researchers in mathematics education have explored and studied a variety of methods to raise the mathematics achievement of African American students using what they term as equitable practices. In this study, I chose not to advocate yet another approach for teachers to use in the classroom. Instead, I qualitatively investigated an elementary mathematics teacher's knowledge of equity in teaching mathematics. I find that teachers who have been successful in teaching mathematics to African American students have productive beliefs about African American students, which influences and are influenced by their knowledge of equity issues and their knowledge of equity pedagogy.

If we want African American students to succeed in mathematics, we need to better understand the necessary knowledge base related to equity in teaching African American students. Currently, equity in mathematics education has not been fully theorized (Gutierrez, 2002). The findings from this study suggest this framework is a constructive approach to theorizing teachers' knowledge of equity in teaching mathematics to African American students.

THE IMPACT OF FAMILY MATH NIGHTS ON PRESERVICE TEACHERS' PERSPECTIVES OF PARENTAL INVOLVEMENT

dross@coe.ufl.edu

This paper describes a Family Math Night designed to engage preservice teachers with parents in a high-poverty, minority setting and presents the results of a pre/post/follow-up survey examining the impact of the experience on preservice teachers' perceptions about low-income parents and their engagement in the education of their children.

Theoretical Framework and Context

There is little controversy about the benefits of parental involvement in children's education. Research indicates clear links between parental involvement and various indicators of school performance such as grades, test scores, graduation rates, and enrollment in institutions of higher education (Epstein & Dauber, 1991; Fan & Chen, 2001; Garcia & Hasson, 2004; Ingram, Wolfe, & Lieberman, 2007). Additionally, research indicates parental involvement impacts attitudes, school attendance, motivation, and behavioral outcomes such as suspensions, drug usage, and violent behavior (Ingram et al., 2007).

Perhaps because the connections between parental involvement and student performance are so strong, teachers often point to the lack of parental involvement as a key factor in poor student performance and in the achievement gap between poor and often minority students and their higher-income peers. Walker (2007) reports a common perception that the lower levels of support provided by low-income parents impedes their children's achievement. For example, educators surveyed about their beliefs regarding the reasons for African American male high school students' low achievement cited home factors as a primary factor (Lynn, Bacon, Totten, Bridges, & Jennings, 2010). Similarly, studies suggest that preservice (Gonzalez & Ayala-Alcantar, 2008) and in-service teachers (Patterson, Hale & Stessman, 2007/2008) attribute poor student performance and behavior to low-income Hispanic parents who, from their perspectives, do not value education and are not involved with the school.

Studies of teachers' perceptions of influences on student achievement in mathematics also point to the significance of parental involvement. Teachers report believing the lack of parental support for schoolwork and mathematics is a significant factor in the achievement gap (Bol & Berry, 2005). Sheldon and Epstein (2005) reviewed literature on mathematics achievement and concluded lack of home involvement is one of four explanations for low achievement. Yet, despite national policy calling for increases in parent involvement (US Department of Education, 2003) and evidence that increasing parental involvement improves students' attitudes toward school and their perceptions of their competence in math (Dearing, Kreider, & Weise, 2008), little attention has been devoted to improving home-school connections as a part of mathematics reform efforts (Sheldon & Epstein, 2005).

Increasing parent involvement requires that teachers believe parents will be involved and work actively to invite and encourage parents (Epstein & Dauber, 1991). Family Math Nights, first described by Stenmark, Thompson and Cossey (1986), are one such strategy for involving families. The goal of a Family Math Night is to help parents and children have fun and build

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

positive connections with school and mathematics. Math games, a carnival-like atmosphere, and the provision of food are an integral part of the event (Hall & Acri, 1995; Kyle, McIntyre, Miller, & Moore, 2006; Taylor-Cox, 2005).

One wonders why Family Math Nights have not become common given the policy imperative to increase family engagement. The challenge, perhaps, is that many teachers believe poor and minority parents will not come, and therefore do use invitational strategies. Additionally, although universities have increased their focus on family involvement in recent years, the dominant focus is on topics like conducting conferences and using volunteers with little focus on skills related to conducting workshops like family nights (Epstein & Sanders, 2006).

Hindered by their assumptions that low-income parents do not value school and/or mathematics achievement and/or by the lack of skills, many teachers fail to invest time in strategies to involve parents. Lachance (2007) incorporated a Family Math Night field component into a preservice course to help teach parent-engagement skills. Participation in the event helped preservice teachers see families having fun and see students' various learning styles that must be accommodated. However, this event was not held in a low-income environment and the impact on preservice teachers' perceptions of parental involvement was not examined.

Practical field-based experience related to family involvement should be a component of preservice preparation programs (Epstein & Sanders, 2006). This paper reports the impact of a Family Math Night field component in a mathematics methods course on preservice teachers' perspectives about low-income African American parents and their engagement in the education of their children.

Methods and Data Sources

Participants

Preservice teachers (64 women, 3 men) in their fourth year of a five year elementary teacher preparation program participated in this study. The median age was 21. The participants came from three sections of an elementary mathematics methods course. Other than participation in the intervention, there were no differences in the content taught across the three sections. One of these was a treatment section (23 women, 1 man) and the other two were control sections (Control A: 20 women, 1 man; Control B: 21 women, 1 man). The majority of participants in each section identified themselves as Caucasian. Of the 24 participants in the treatment group, 18 (17 women, 1 man) responded to a follow-up survey one year later.

Intervention

The treatment group participated in a Family Math Night held at a local elementary school that serves a predominately African American (92%) community; 86% of the students receive free/reduced lunch. The school has been one of the lowest performing schools in the area according to the State Assessment System.

All students, their parents and other family members, were invited to attend. Food was provided at no charge. Students and their families were given free tickets, which they turned used to play a game. After completing a game, they were given raffle tickets for a door prize drawing. These characteristics of the event, as well as rigorous advertizing and responsiveness to parent needs, encouraged parents to attend, and created a fun atmosphere in which families could interact.

The Family Math Night was held approximately midway through the semester. Approximately 200 students and families attended. As a component of the course, members of the treatment section were required to participate. They were provided instructions for the games, assisted with preparation. Their role was to coordinate games on the evening of the event. Preparation of participants prior to the event focused on their role in facilitating the games. They were coached on how they should model the games, and how to explain the games to parents so they would be able to utilize similar games at home. The focus on the preparation activities was not on the games themselves, but rather on the idea that the preservice teachers should interact with parents in an engaging and non-threatening manner. At the event, attendees were provided with handouts that described the purpose of each game along with suggestions on how similar games could be played. The participants in the treatment group were encouraged to use this handout to facilitate parents' ability to transfer their experiences at the Family Math Night into mathematics activities at home.

Measures and Procedures

Participants in both the treatment and control groups completed a survey about their perceptions of parental involvement prior to and after the event (see Fig. 1). A follow-up online survey was administered to participants in the treatment group approximately one year later to determine if the changes observed were sustained after participants left the treatment and completed full time internship experiences.

Gender:_______________________________ Race: ____________________

In a POVERTY school, how many of the students' parents do believe will do each of the following?	**None**	**About 25%**	**About 50%**	**About 75%**	**Almost 100%**
1) Do an at home game or activity with their child					
2) Attend parent-teacher conferences					
3) Attend school activities such as PTA meetings and Family nights					
4) Communicate the importance of completing homework to their student					
5) Assist students with homework					
6) Examine completed work that the student brings home					
7) Ask you for ideas about how to help their child at home					

Figure 1. Pre/post survey used for data collection.

Results

Treatment and Control Groups Comparison

A Chi-Square test was used to determine whether there were differences between the treatment and control group before and after the intervention. There were no significant differences between the three groups on the pretest. However, there were four significant differences observed on the posttest. All differences were in the positive direction, demonstrating changes in perceptions of parents' willingness to: 1) to do an at home game or activity with their child (Chi-square(6)=13.09, p=0.04); 2) attend parent-teacher conferences (Chi-square(8)=15.35, p=0.05); 3) attend school activities such as PTA meetings and Family Nights (Chi-square(6)=26.89, p<0.001); and 5) assist students with homework (Chi-square(6)=11.81, p=0.07).

Treatment Pretest and Posttest Analysis

The Shapiro-Wilk test for normality was used to determine if a dependent t-test would be appropriate to explore differences between the pretest and posttest data within the groups. This test, as well as exploration of the graph of the normal probability plot and frequency distribution histogram, revealed that the data violated the normality assumption. Therefore the Wilcoxon Signed-Rank Test, the non-parametric equivalent to the t-test, was used to analyze the data. There were no significant differences between the pretest and posttest data for the control groups. In the treatment group, significant differences were observed on six of seven questions. All differences were in the positive direction, demonstrating changes in perceptions of parents' willingness to: 1) to do an at home game or activity with their child (Z=-2.92, p=0.003); 2) attend parent-teacher conferences (Z=-1.72, p=0.085); 3) attend school activities such as PTA meetings and Family Nights (Z=-2.62, p=0.009); 5) assist students with homework (Z=-2.43, p=0.015); 6) examine completed work that the student brings home (Z=-2.24, p=0.025); and 7) ask for ideas about how to help their child at home (Z=-2.55, p=0.011).

Treatment Pretest, Posttest, and Follow-Up Analysis

Due to similar conditions considering the normality of the distribution of the responses on the follow-up tests, the Wilcoxon Signed-Rank Test was used to compare the pretest, posttest, and follow-up test data. Three separate tests were performed to compare: 1) pretest to posttest data; 2) pretest to follow-up test data; and 3) posttest to follow-up test data for the 18 participants who completed the follow-up questionnaire.

On the pretest and posttest analysis, significant differences were observed on five questions. The question that did not have a significant difference on this analysis, but did in the analysis of the entire treatment group, was the one concerning parents' willingness to attend conferences. All significant differences were in the positive direction and related to parents' willingness to: 1) to do an at home game or activity with their child (Z=-2.23, p=0.026); 3) attend school activities such as PTA meetings and Family Nights (Z=-1.98, p=0.048); 5) assist students with homework (Z=-1.71, p=0.088); 6) examine completed work that the student brings home (Z=-1.73, p=0.083); and 7) ask for ideas about how to help their child at home (Z=-1.77, p=0.077).

On the pretest and follow-up analysis, significant differences were observed on only one question. This difference, again in the positive direction, was related to parents' willingness to: 7) ask for ideas about how to help their child at home (Z=-1.89, p=0.059).

There was also only one significant difference in the analysis of the posttest and follow-up test data. This difference occurred in the negative direction with the ratings dropping significantly from the posttest to the follow-up. This question related to parents' willingness to: 3) attend school activities such as PTA meetings and Family Nights (Z=-2.14, p=0.033).

Educational Significance

Parents play an important role in their children's academic success (Epstein & Dauber, 1991; Fan & Chen, 2001; Garcia & Hasson, 2004; Ingram et al., 2007), yet teachers often believe low-income, minority parents to blame for the achievement gap and don't reach out and encourage their participation (Bol & Berry, 2005; Lynn et al., 2010; Gonzalez & Ayala-Alcantar, 2008; Patterson et al., 2007/2008; Walker, 2007). These beliefs are neither productive nor professional, and must be remedied. The results of this study support previous research (e.g. Philipp et al., 2007) that coursework coupled with fieldwork can have a strong impact on preservice teachers. The participants who attended Family Math Night had more positive views toward low-income, minority parents and their involvement in their child's education than their peers. These effects, however, were not sustained after their internship experience, where they had very little control over interactions with parents and where events such as Family Math Night were not held. This suggests that sustained change in preservice teachers' beliefs about parental involvement may require multiple field experiences with opportunities for positive engagement with parents.

ENGAGING IN MATHEMATICALLY-RELEVANT PLAY WITHOUT SIGHT

Joanne Lee

castordy@gmail.com

This research examined whether mathematically-relevant play between a mother with a visual impairment and her sighted 15-month-old daughter could be facilitated by a five-week community-based early numeracy program. We aimed to identify the similarities and differences in mathematically-relevant input by comparing the 30-minute naturalistic free-play session conducted separately between the mother-daughter dyad and the sighted father-daughter dyad. Our findings reveal that the mother produced fewer mathematically-relevant utterances than the sighted father who did not participate in the early numeracy program. Implications for engaging in mathematically-relevant input by parents with a visual impairment with their sighted toddlers will be discussed.

Introduction

Empirical evidence suggests that the human brain is hardwired to engage in mathematical ideas and concepts (Butterworth, 1999; Dehaene, Molko, Cohen, & Wilson, 2004; Dehaene, Spelke, Stanescu, Pinel, & Tsivkin, 1999). However, empirical evidence also points to the critical importance of the environment on mathematical development. Parents and other significant adults have a pivotal role in supporting children's early mathematics development during the period between ages one to three years old. For example, parental or significant adults' teaching of mathematical concepts such as counting or providing mathematically-rich input has been found to relate to children's emergent numeracy skills (Klibanoff, Levine, Huttenlocher, Vasilyeva, & Hedges, 2006; LeFevre, Clarke, & Stringer, 2002; Saxe, Guberman, & Gerhart, 1987). Mathematically-relevant input, as used in this context includes instances of joint attention between a caregiver and a child that mathematize elements of play, or engage in explicit mathematical play (e.g., counting, comparing, ordering, etc.) (van Oers, 1996). Additionally, mathematically-relevant input includes mathematical talk or language, as well as gestures (Klibanoff et al., 2006; Lee, Kotsopoulos, Tumber, & Dittmer, 2009; Nührenbörger & Steinbring, 2009; Singer, Radinsky, & Goldman, 2008).

Very few studies have examined adult mathematically-relevant input children receive at home on numeracy during their first few years of life. The few existing studies using interviews and checklists suggest that parental mathematical input is related to four- and five-year-olds' level of number knowledge, such as knowing differences in quantities and that numbers have magnitudes (e.g., Saxe et al., 1987; Blevins-Knabe & Musun-Miller, 1996; LeFevre, Clarke & Stringer, 2002). Given existing evidence on the importance of mathematically-relevant input in the environment for supporting the further development of mathematical understanding in young children, this research contributes to the dearth of studies by identifying (a) the nature of the mathematically-relevant input provided by parents with a visual impairment, and (b) how early educational programs such as LittleCounters™ (a community-based early numeracy program for parents with children between 12 and 36 months old, Kotsopoulos & Lee, 2009) could be tailored to overcome the challenges posed by visual impairment.

Our research questions for this case study were as follows: (1) Were there observational differences in the nature of mathematical talk during play between the parent-child dyads (mother-child versus dad-child)? (2) What are the potential learning implications of those differences (or not) for the sighted children of parents who are visually impaired?

Theoretical framework

Vision is important to the communicative and language development. It provides the ability of both the caregiver and child to be in tune with one another during conventional and normal cycles of interactions. Mutual gaze and visual exchange are important actions made to convey and understand messages during early communication, between parents and their sighted infants (Kekelis & Andersen, 1984; Rowland, 1984). Vision, is often seen as the primary integrative or mediating mode of communication. Visual information (i.e., eye gaze and gestures) aids the caregivers in understanding, interpretation and appropriately responding to their children's early speech or language (Kekelis & Andersen, 1984).

Maternal visual status has been found to influence children's early communicative development such as infant vocalizations (Rattray & Zeedyk, 2005). Infants of sighted mothers were found to be more vocal than infants with mothers with a visual impairment, particularly after 14 months of age (Rattray & Zeedyk, 2005). To date, most studies on visual impairment have focused on infants with the impairment and their language development. To the best of our knowledge, there is no known published research that examines how parental visual impairment would influence the provision of a mathematically rich environment for their sighted children, and might subsequently influence their children's mathematical development. The importance of the amount of mathematical talk children receive in the daily lives during the early years of life and its impact on their acquisition of mathematically language and concepts must be underscored. For example, developmental studies suggest that early mathematics representations such as numerosity (1 unit or 2 units of something) are linked to mathematics language, for example, the knowledge of count words (e.g, *one* and *two*) (e.g., Huttenlocker et al., 1994; Jeong & Levine, 2005). Thus, we currently do not have a good overview of what kind of mathematical talk young toddlers receive at home under the care of parents with a visual impairment.

The descriptive sentence 'parents leading from behind' becomes a very important reference in relation to caregivers doing more than just acknowledging or interpreting their child's communication attempt such as putting gesture into words, expanding on two-word utterances into complete sentences, and adding descriptive labels for him/her (Bruinsma et al., 2004; Kekelis & Andersen, 1984). Caregivers are teaching their children how to expand on ideas during speaker's turns, as well as how to respond contingently to their partner. Though existing research has been conducted on children with a visual impairment and their parents with sight, measurable research pertaining to visual impairment and parent-child dyads involving communication via gesture, speech, and touch does not examine how a child acquire linguistic and mathematical concepts with a parent who is visually impaired during the early stages of development (Bruinsma et al., 2004; Colombi et al., 2009; Kekelis & Andersen, 1984; MacDonald et al., 2006).

By examining the interactions between the two caregivers and their sighted daughter in a free play session with a standard set of toys picture books, differences in the quality of talk in terms of introducing mathematical-related words (e.g., '*one, two, three*', '*how many*') could be identified. The free play sessions were able to capture both the verbal and nonverbal ways in which mathematical words are presented to the child. Without the need for questionnaires or checklists that rely on parental memory, this approach allows us to examine the input that occurred in a more naturalistic manner and to obtain the frequency and nature of incidental mathematically relevant input that the child received at home with her parents.

Method

Participants

The current case study included a family of three individuals: a mother (age 32), a father (age 29), and a female child (15 months during the first home visit with mother and 19 months during the second home visit with father). The mother was born sighted. Due to a medical condition, she lost partial vision by eight years old before losing it completely at the age of ten. The mother is bilingual and speaks both English and Polish to her daughter. The father is a sighted Chinese-Canadian, currently working as a lawyer and only speaks English to the daughter. Both parents are highly educated and have completed four years of university education. The mother has completed three years of graduate work and the father has completed two years of professional work as a lawyer. The mother has reported informally that her sighted daughter is able to understand both English and Polish words, although she has yet to produce many words in either language.

Both parents engaged in a separate (mother-daughter dyad and father-daughter dyad) 30-minute naturalistic free play session in their home with the child. The first 30-minute naturalistic free play session occurred between the mother-daughter dyad in their home when the child was 15 months of age. The second 30-minute naturalistic free play session occurred approximately four months later between the father-daughter dyad in their home when the child was 19 months of age. The four-month interval between the two play sessions was due to the busy schedule of the father and the family's move to a new house. The family received a $10 gift card for their participation.

The mother and child participated in the LittleCounter™ program (Kotsopoulos & Lee, 2009) at a local library. As a result of participating in the program and the case of a caregiver with a visual impairment, the family was recruited for the current case study. In addition to participating in the LittleCounters™ program, the child was involved in other local community activities (e.g., educational programs) with the mother for approximately five to six hours a week, but does not attend daycare. The maternal grandparents, who speak Polish, also provided respite care to the child during the week.

Early Numeracy Program

The LittleCounters™ program consisted of five, 45 minute sessions (10:00 a.m. to 10:45 a.m.) over a span of five weeks at a local library. This community-based early numeracy program is offered free to families with young children between 12 and 36 months old. The goal of the program is to teach parents how to integrate mathematical relevant input into their child's play through the use of songs, games, stories, and movements. Supporting the development of the counting principles (i.e., stable order, one-to-one correspondence, order irrelevance, cardinality, and abstraction) was the basis of each of the five sessions. Additionally, a different mathematical concept is featured during each of the sessions: cardinality (i.e., last number represent counted represents total in the set), magnitude (i.e., more or less), ordinality (i.e., first, second, third, etc.), internal number line (small to large, left to right) and spatial effects (i.e., difference between bigger in size versus more in quantity), and parity (i.e., equal or the same).

For each of the sessions that the mother attended with her daughter, an instructor's aide (the third author) was by the mother's side to directly assist her with the activities of the program.

The instructor's aide assisted with the mathematical play and also ensured that the daughter was safe as she moved around the room independently.

Materials & Procedure

For the play session at home, in order to reduce variability between the activities in which the mother-daughter dyad and the father-daughter dyad engaged in, each dyad was provided with a standard set of toys. The toys included: four hand puppets, four oversized foam dice, one toy truck, three backpacks, a shape sorter bucket with plastic shapes (four green squares, four red triangles, and three blue circles), 40 small transportation toys (fire trucks, school buses, trains, cars, planes, and boats), 40 small animal toys (horse, cows, calves, pigs, piglets, ducks, rabbits, and sheep), 68 foam blocks in a variety of shapes (17 yellow, 17 blue, 17 red, 17 green), two children's pop-up books (one on color and one on numbers), three plastic squares, three plastic triangles, three plastic circles, three plastic rectangles (one blue, one yellow, and one red of each shape). The mother was told orally about the toys and invited to touch the toys prior to commencing.

Transcription and Coding

Each free play session of the parent-child dyads was videotaped, transcribed and coded using a portable Observer XT system (Noldus Information Technology, 2009) that allows the experimenters to work the two cameras using a remote control in a separate room from the dyad. The parent-child dyad was also asked to wear a wireless microphone each to ensure a high audio quality. Such an arrangement ensured that the free play session was as naturalistic as possible.

For the current research, mathematically-related talk referred strictly to utterances produced by parents and children to denote mathematical relations such as cardinality and quantity. All the adult speech were transcribed and coded by two trained research assistants for the mathematically-related input in the following categories: i. quantity or equivalence/non-equivalence words (e.g., how many, less than, more), ii. counting words (e.g., one, two), iii. counting objects in an array or in sets, iv. cardinality (stating or asking for the number of items in a set without counting), v. transformation of object arrays involving addition or subtraction (e.g., "If one cow went missing, how many do you have now?"), and vi. ordering numbers (e.g., 'Three, what comes after three?'). The coding scheme was adapted from Klibanoff, Levine, Huttenlocher, Vasilyeva, and Hedges (2006). Additionally, nouns and verbs used outside the context of mathematically-relevant input were also coded to account for the amount of non-mathematically-related talk.

Table 1. Coding scheme of mathematically-relevant input

Quantity or Equivalence/nonequivalence words	• How many, how much, so much, several, some, a few, altogether, most, more, same (only in the context of quantity, and not in the other context such as color), greater than, less than, count, lots, another, all, ones, all, some, little, little bit, a little, any, a couple, bunch… (Note: “match” or “anything else” are not quantity words)
Counting words	• Recite counting words such as ‘one’, ‘two’, ‘three’ (Similar to reciting the alphabets) • Count each word said as one occurrence. E.g., If the caregiver says “One, two, three”, count = 3, and not 1 because there are three count words in the utterance. • Number words such as ‘one’, ‘two’… Not associated with an object or an array of objects.
Counting objects	• Counting objects in an array or in sets (1,2,3,4..)
Cardinality words	• Stating or asking for the number of things in a set without counting them (e.g., Point to the child the number ‘2’ and ask him/her to point or show two items/objects or the above example “There are 3 books.”) • The number word (‘one’, ‘two’..) here is associated with an object or a set of objects (E.g., ‘SIX sides of a cube’, ‘THREE trucks’) • No counting involved
Transformation of object arrays	• Add, subtract, take-away (e.g., “If you take away from three, how many do you have?”) OR • One object item removed from an array of objects (e.g., 1 bird flew away, how many are left?)
Ordering numbers (different from reciting a list of number words)	• “Three, what comes after three?’

Results

Both parents produced more non-mathematically-relevant input than mathematically-relevant input during their 30-minute play session with their toddler. Since the daughter did not produce any words during both sessions, we did not include any of her data in Table 1. The coding of both visits by both coders individually was checked for inter-coder reliability by calculating the Cohen's Kappa and the population coefficient (Rho) for the entire 30-minute free-play session: the mother-daughter dyad (Kappa 0.83, Rho 0.99), the father-daughter dyad (Kappa 0.88, Rho 0.99). In terms of mathematically-related input, our results indicate that only two categories – counting and quantity words were produced by the parents. Though the mother with a visual impairment attended the 10 sessions of the LittleCounters TM program, she produced fewer instances of both counting and quantity words than the father with sight, who did not participate in the early numeracy program. A recent study on mathematically-relevant input produced by 19 sighted parents with 12 girls and 7 boys (with a mean age of 21.08 months, *S.D.* = 4.32) that have participated in the LittleCounters^{TM} program revealed that these parents produced an average of 9.84 counting words and 48.42 quantity words (Lee et al., 2010).

Table 2. Instances of word categories produced

Participants	Nouns	Verbs	Counting words	Quantity words	Total
Father	152	140	28	34	354
Mother	79	92	1	17	189
Total	231	232	29	51	543

Discussion

To begin our discussion, it is important to note that existing research on parents with a visual impairment who have children with sight has predominantly focused on practical considerations of parenthood such as caring for the infant. Our research examined the play environment between a caregiver (mother) with a visual impairment and her sighted 15 month-old daughter to explore the extent to which mathematically-relevant input was observed. Our findings did not suggest that the mother applied any skills taught within the two five-week sessions (10 sessions in total). Other related research on the LittleCounters^{TM} program has shown that participating parents produce more mathematically-relevant input than parents who have not participated in the program, over the same observation period (i.e., 30 minutes), using the same set of toys and books provided and the same research methodology (Lee et al., 2010).

Our findings also raise some questions in terms of the LittleCounters^{TM} program. Although an instructor's aide was provided to assist the mother during each of the sessions, perhaps the type of support was not consistent to what may have actually been necessary. For example, the support for the parent could have included building in strategies, with the parent's input, on ways in which the parent could communicate to the child on a particular object. Additionally, more hand-on-hand instruction for both the parent and the child could have been useful. Strategies for showing approval to the child could have also been useful. For example, when engaging in counting of fingers, we could have had all families stop to physically touch each other's fingers to ensure that the appropriate amount of digits was shown. It is possible that we may have relied too much on gesture and vocalization during our sessions which may not have been sufficient for a parent with a visual impairment.

Several studies have reported that mathematically-relevant input increases mathematical ability in young children (Klibanoff et al., 2006; Miller et al., 2000). Although this research is a case study, it provides us with a rare opportunity to examine the nature of the play environment between a mother with a visual impairment and her sighted child. For example, our results raise some concern over the level of cognitive engagement, particularly mathematically-relevant engagement that a child of a parent with a visual impairment may receive. Future policy and support directions could include provisions for providing additional resources to support parents during the crucial early developmental periods of childrearing. The early years of life have increasingly been found to be crucial in success or failure in formal schooling (Heckman, 2004).

Parents with a visual impairment could provide mathematically-relevant input by engaging in more "give me" instead of "can you show me" task during play. For example, a parent with a visual impairment, who is looking to determine whether a child understands one-to-one correspondence (one object is counted once), may need to hold the child's hand while doing the task to check the child's understanding. In sum, parents with a visual impairment may require additional coaching and support to learn how to assist young children during early childhood where shared understanding is much dependent on vision and gesture.

Acknowledgments

This research was funded by Social Sciences and Humanities Research Council of Canada, Canadian Foundation for Innovation, Ontario Research Fund, and the Fields Institute for Mathematical Sciences. We wish to thank Anupreet Tumber for her assistance in the Observer XT program and Alex McGregor for his assistance in coding the play sessions.

HOW STEREOTYPE THREAT AFFECTS FEMALE MATHEMATICAL PERFORMANCE

Bryan Nankervis
Texas State University-San Marcos
bn10@txstate.edu

Stereotype threat has been shown to undermine the achievement of women within the domain of mathematics. This paper will review studies relevant to conditions that give rise to stereotype threat in women, types of mathematical tasks that are susceptible to stereotype threat, how stereotype threat interrupts performance, and interventions which lessen the effects of stereotype threat. Research on this phenomenon has far-reaching implications, not only for women, but also mathematics educators and university administrators as stereotype threat has been shown to account for most of the gender gap on the SAT, which in turn directly affects admissions and eligibility for scholarships.

Introduction

Performance differences between the sexes across mathematical content areas, problem types, and various instruments have been documented (Gallagher & Kaufman, 2005; Hyde, Fennema, & Lamon, 1990; Paek, 2002; Willingham & Cole, 1997), and in some situations these differences may be due to a lack of opportunity to learn about particular mathematical topics on the part of females. However, it has also been demonstrated that stereotype threat can contribute to performance gaps by causing equally qualified females to falter in the face of complex numerical reasoning tasks or word problems and opt to guess at an answer while their male counterparts are unaffected (Quinn & Spencer, 2001; Spencer, Steele, & Quinn, 1998). This paper brings together studies on stereotype threat, its affect on women's problem-solving strategies, the interaction between stereotype threat and cognitive capacity, and interventions which can limit the influence of stereotype threat on women.

Theoretical Perspectives

A landmark study (Steele & Aronson, 1995), that introduced the term *stereotype threat,* presented a possible explanation for some of the differences in achievement between males and females exhibited on mathematics assessments. Stereotype threat is defined in this study as a feeling of "being at risk of confirming, as self-characteristic, a negative stereotype about one's group." Further, it is stated that stereotype threat "may interfere with the intellectual functioning of these students [affected by stereotype threat], particularly during standardized tests" (Steele & Aronson, 1995, p. 797). This initial study focused on Black students who are stereotypically considered less able than White students in terms of general intellectual aptitude.

In the study, the researchers, working with a group of Black and White students, explicitly "primed" the stereotype for one subgroup of students (the experimental group) before administering the SAT verbal test. Specifically, before the experimental group took the exam, the researchers told them of historical diagnostic differences (that Blacks had generally scored lower on this test than Whites and that the test was diagnostic of ability). As a result, the Blacks in the "ability-diagnostic" group significantly underperformed (as measured by their previous SAT scores), while Blacks in the control or "nondiagnostic" group did not (Steele & Aronson, 1995).

The findings of Steele and Aronson's seminal study are relevant to research on performance gaps between the sexes on standardized mathematics tests since females must also deal with stereotype threat. In particular, females are susceptible to the stereotype that they are publicly perceived to be less able in mathematics than males. Steele and Aronson note the broad applicability of stereotype threat: "This threat can befall anyone with a group identity about which some negative stereotype exists, and for the person to be threatened in this way, he [or she] need not even believe this stereotype" (Steele & Aronson, 1995, p. 798).

The effects of stereotype threat on women's mathematics performance were later confirmed among college females who excelled at math and identified strongly with the subject (Spencer, Steele, & Quinn, 1998). In this study, on a relatively difficult test (composed from the advanced GRE [Graduate Record Examinations] in mathematics), females underperformed compared to males when informed before they took the test of historic sex differences in test performance, while they performed on par with males when told that the test was gender-insensitive. This study's findings confirmed what Claude Steele had concluded in an earlier article: That "stereotype threat may be a possible source of bias in standardized tests, a bias that arises not from item content but from group differences in the threat that societal stereotypes attach to test performance" (Steele, 1997, p. 622).

A test item can be linguistically biased if it uses terms that are unfamiliar to some subgroups, while the overall content of an item might be biased if it refers to situations that are less familiar for certain subgroups (Hambleton & Rodgers, 1995). While bias in item content has been confirmed and addressed by test developers over the years, the effects of stereotype threat are situational (dependent on the testing environment) and cannot be remedied by simply changing the language or premise of specific test items. One study (Shih, Pittinsky, & Ambady, 1999), that demonstrates the situational aspect of stereotype threat, examined the effects of racial and gender stereotype threat combined. While Asian-American women are stereotyped positively in mathematics due to their ethnicity, they are stereotyped negatively because of their sex. On a standardized mathematics test (SAT I quantitative section) given to Asian-American women, those whose ethnicity was primed performed better, and those whose gender was primed performed worse, than a control group for whom neither attribute was made salient (Shih et al., 1999).

A similar boost in achievement due to a positive stereotype was also observed in previous studies for White students when race was primed (Steele & Aronson, 1995) and for males when gender was primed (Spencer et al., 1998). This potential positive effect of certain stereotyping is supported by social cognitive theory: "Indeed, people who believe strongly in their problem-solving capabilities remain highly efficient in their analytic thinking in complex decision making situations, whereas those who are plagued by self-doubts are erratic in their analytic thinking," and "when faced with difficulties, people who are beset by self-doubts abort their attempts prematurely and quickly settle for mediocre solutions, whereas those who have a strong belief in their capabilities exert greater effort to master the challenge" (Bandura, 1989, p. 1176). This boost in performance for test-takers who are not part of the negatively stereotyped subgroup has been referred to as *stereotype lift*. A meta-analysis of 43 studies found that merely representing tests as diagnostic of ability was enough to induce stereotype lift in non-negatively stereotyped subgroups. Further, while the average effect size of stereotype lift (d =.24) was only half that of stereotype threat (d =.48) in these studies, it was still substantial (Walton & Cohen, 2002).

Stereotype threat can be primed in various ways. One is under the condition of *evaluative scrutiny*. In this situation test-takers know their results will be available to others, such as parents, teachers, administrators, or colleges. On standardized tests such as the SAT or ACT, some degree of evaluative scrutiny is always present. Another way to induce stereotype threat is via the condition of *identity salience*. This condition can be thought of as “the likelihood that the identity will be invoked in diverse situations” (Hogg, Terry, & White, 1995, p. 257). Participating in a mixed testing environment (e.g., males and females together) or having to identify one’s sex prior to a standardized test, as is often the norm, can cause one’s identity to become salient.

The effects of identity salience have been measured in studies conducted by the Educational Testing Service, commonly known as ETS, and the College Board. In one experiment, researchers administered the mathematics section of the GRE general test to males and females on an *individual* basis (GRE Board, 1999). In this study, the gap in scores between males and females was less than half that from the regular administration of the GRE general test (d =.40 versus d =.97) that same year, in which students generally tested in a mixed environment.

Another study measured the effect on performance from identifying one’s sex before a test (College Board, 1998). The experiment focused on students taking the Advanced Placement Calculus AB exam, and for those who indicated their sex on a standard background information sheet before the test, the performance gap effect size between males and females (d = .41) was more than triple that for those who identified their sex after the test (d = .12). These studies clearly demonstrate that while subtle in nature, the condition of identity salience can induce stereotype threat and thus cause women to underperform on standardized mathematics tests. A more recent study has actually measured the effects of stereotype threat on females’ SAT performance and found that it accounts for the majority of the gender gap on the quantitative section. In particular, the researchers (Walton & Spencer, 2009) found that stereotype threat is responsible for 19-21 points of the 34 point difference in scores between men and women.

Differences in Strategies Used by Males and Females under Conditions of Stereotype Threat

A study by Quinn and Spencer (2001) attempted to replicate a previous Gallagher and De Lisi (1994) experiment, which looked at the kinds of strategies employed by males and females when solving SAT I mathematics word problems. Gallagher and De Lisi found that females relied more on conventional strategies, while males resorted to using more unconventional strategies. Quinn and Spencer (2001) found further that a significant number of females were unable to come up with any problem-solving strategy at all.

In the second part of Quinn and Spencer’s study, when stereotype threat was primed by evaluative scrutiny and identity salience, females underperformed compared to males on a test of all mathematical word problems, but not on a test of the same problems reduced to their numerical equivalents (that is, no words, just equations). Quinn and Spencer concluded that stereotype threat lowered women’s mathematics achievement by hindering their capacity to generate and use problem-solving strategies (2001). They suggested that women had a diminished cognitive capacity as a result of having to deal with the effects of stereotype threat.

On the surface, the results of this part of Quinn and Spencer’s study might seem contradictory, since women, due to their documented edge in verbal skills, would seem to be favored in the domain of word problems. In this part of the study, however, the reason for women’s underperformance seemed to lie in difficulty with the processes and strategies of converting word problems into equations (Quinn & Spencer, 2001). Since then, another study (Bielock, Rydell, & McConnell, 2007) has confirmed that in particular, stereotype threat most greatly affects women’s performance on mathematical problems that rely heavily on verbal working memory resources. It was also demonstrated in this study that underperformance can *spillover* to tasks outside the domain of the stereotype that are reliant on verbal working memory resources (Bielock, Rydell, & McConnell, 2007). This may help to explain why women, who traditionally perform better than men on tests of verbal skills, score lower than men on the SAT critical reading exam, which is taken in conjunction with the SAT mathematics exam.

How Cognitive Capacity Interacts with Stereotype Threat

The human mind has been described as a "limited-capacity information processor" (Weinstein, 2005), and the attempt to control one's mental state can be broken down into the two processes of operating and monitoring (Wegner, 1994). Wegner notes that the operating process "promotes the intended change by searching for mental contents consistent with the intended state" of mind, while the monitoring process "tests whether the operating process is needed, by searching for mental contents inconsistent with the intended state" of mind. Both processes working together provide an individual's mental control and since these processes share the same mental space, at times (for example, when the mind is working on difficult or complex tasks) they must compete for limited mental capacity. Under conditions that reduce capacity, the monitoring process may override the operating process and thus lessen a person's focus on their intended task. Thus, the operating process is susceptible to distractions, either in the form of stress or from multitasking. "Anything that distracts the person's attention from the task of mental control will undermine the operating process and so enhance the effect of the monitoring process" (Wegner, 1994, p. 40).

Arousal plays a major role in many learning theories and is affected by levels of anxiety and stress. The Yerkes-Dodson Law, which describes the psychological effects of physiological arousal on performance, says that with appropriate levels of arousal, performance increases, but that when levels of arousal are too low or too high, performance decreases. The law (it is referred to as a law because the results of Yerkes and Dodson's experiments have been replicated numerous times since the original study) suggests that an inverted U-shape describes the relationship between arousal and performance (Yerkes & Dodson, 1908). At low levels of arousal, the subject (in our case, a student) is simply not motivated enough to perform well, while moderate levels of arousal are healthy and conducive to optimal functioning.

However, overarousal, caused, for example, by anxiety or stress, can negatively affect performance physiologically, cognitively, and psychologically. It can disrupt physiological states when the body reacts to stress by releasing hormones from the adrenal medulla (adrenaline) and the adrenal cortex (cortisol). This hormone release in turn increases heart rate, respiration, and blood pressure, which leads to hyperactivity (Selye, 1956). In addition to these physiological symptoms, cognitive activity can be disrupted via forgetfulness, confusion, and an inability to concentrate as a result of overarousal (Broadbent, Cooper, FitzGerald, & Parkes, 1982).

Overarousal can also disrupt emotional states through anxiety. It has been shown that overanxious persons entertain more task-irrelevant thoughts than nonanxious persons, and that these thoughts are frequently focused on negative personal characteristics, most notably during ability assessments such as achievement tests (Wigfield & Eccles, 1989). In particular, overarousal in the form of anxiety as a result of stereotype threat conditions has been shown to accompany the underperformance of females on standardized mathematics tests (Harder, 1999; Spencer et al., 1998). Further, it has been demonstrated that anxiety and evaluation apprehension are significantly related to females' performance on such tests (Spencer et al., 1998). Bandura (1989) states in an article on human agency that "threat is a relational property concerning the match between perceived coping capabilities and potentially aversive aspects of the environment," and "those who believe they cannot manage potential threats experience higher levels of stress and anxiety arousal" (p. 1177).

There is also evidence to support the notion of decreased performance for females under stereotype threat conditions (because available capacity for the operating process is reduced due to an increase in the monitoring process) in terms of working memory capacity. Working memory capacity can be thought of as the ability to maintain focus on a particular task while disregarding competing irrelevant thoughts (Engle, 2001). It is strongly related to performance on complex cognitive tasks such as problem solving. One study found that a measure of working memory capacity correlates significantly with scores on both the quantitative and the verbal sections of the SAT I (Turner & Engle, 1989). That is, those with more working memory capacity tended to perform better on these SAT I sections. Furthermore, there is strong evidence that "stereotype threat reduces an individual's performance on a complex cognitive test because it reduces the individual's working memory capacity" (Schmader & Johns, 2003, p. 449). A recent study suggests that, in particular, stereotype threat undermines performance through physiological stress, attempts to curb negative thinking, and an overactive monitoring process (Schmader, Johns, & Forbes, 2008).

The general notion that stereotype threat reduces cognitive capacity is supported by the results of earlier mentioned studies on sex differences in use of strategies on standardized mathematics test problems. In particular, these study results indicate that females rely more on standard classroom-presented algorithms, while males more often use unconventional strategies or short cuts (Gallagher, 1992; Paek, 2002). This difference might suggest that while females were limited to standard algorithms as a result of diminished cognitive capacity (caused by anxiety induced by stereotype threat), males had either more cognitive capacity available or a less distracted focus, which allowed them access to other, more direct methods to solve problems.

Females have also demonstrated less prior knowledge and fewer strategies than males who had similar mathematical backgrounds when working mathematics problems in mixed testing situations (e.g., males and females in the same group) (Byrnes & Takahira, 1993). This difference again could suggest that females in these situations may have been the victim of reduced working memory capacity. Another study of strategy use, based on mathematics items from the SAT I and the GRE general test, found that males had more strategy flexibility, and, as a result, outperformed females (Gallagher, De Lisi, Holst, McGillicuddy-De Lisi, Morely, & Cahalan, 2000). This greater flexibility demonstrated by males could also suggest that they had more cognitive capacity available than females burdened by stereotype threat resulting from mixed testing situations.

Along with stereotype threat, the rigor associated with a standardized test plays a major role in affecting the amount of cognitive capacity available. It has been documented that gender gaps in mathematics achievement widen as the difficulty level of problems increases (Feingold, 1988). The work by Spencer and colleagues (1998), described earlier, provides further support for this idea. The first part of their study focused on males and females who had performed well, both in a college calculus course (receiving a final grade of B or better) and on the SAT I or ACT quantitative sections (scoring above the 85th percentile). The control group was given a relatively easy (for their background) test (composed from the quantitative section of the GRE general exam), while the experimental group was given a difficult test (composed from the advanced GRE exam in mathematics). Although identity salience (from mixed gender testing) was a condition for females in both the “easy” and the “difficult” test groups, females underperformed compared to males only on the more rigorous test (Spencer et al., 1998). For these high-ability students, the general GRE quantitative section was not as challenging and made fewer demands on their cognitive capacity, which allowed the females to deal effectively with any intrusions by stereotype threat. The more rigorous test, however, required greater cognitive resources which due to stereotype threat were not fully available to the women.

Interventions that Mediate the Effects of Stereotype Threat

In this same group of studies (Spencer et al., 1998), the researchers sought to find out what would happen when they told an experimental mixed group of students in advance that the test they were about to take was insensitive to sex differences. As with the previous study, all the students were subject to identity salience from the mixed testing environment, but those who were *unprimed* (experimental group) exhibited no differences in achievement between males and females, while in the control group (students who were told nothing prior to the test) males outperformed females. McGlone and Aronson (2006) found that getting females in a mixed testing situation to consider positive personal attributes (such as their status as students at a select school) resulted in improved scores on the Vandenberg (Vandenberg & Kuse, 1978) mental rotation test. Seemingly, these types of interventions help to ease the condition of identity salience, thereby lessening the effects of stereotype threat. Further, it has been shown that practicing representative tasks prior to testing, thus moving the knowledge of procedures and concepts to long-term memory from the working memory, also moderates the effects of stereotype threat and improves female performance (Bielock et al., 2007)

Conclusion

Stereotype threat has been shown to have an effect on both the problem-solving strategies of females (Quinn & Spencer, 2001; Bielock et al., 2007) and their cognitive capacity (Turner & Engle, 1989; Schmader & Johns, 2003). However, various types of interventions have proven successful in mitigating the effects of stereotype threat (Spencer et al., 1998; McGlone & Aronson, 2006; Bielock et al., 2007). Even so, there has been little effort to date on the part of those who administer high stakes, standardized mathematics assessments or those who rely on the outcomes of such instruments to recognize or deal with existing inequities.

Approximately 92 % of four-year institutions require SAT/ACT scores from potential students and 75% routinely use these scores in making decisions on admissions (College Board, 2002). SAT scores also play a significant role in many institutions’ scholarship decisions. Likewise, AP and GRE scores play a role in students’ access to undergraduate and graduate education. The common thread between all these instruments is that they are high stakes assessments produced by the College Board and its psychometricians and they all exhibit significant gender gaps favoring males in mathematics that are not reflected in students’ future college performance (Bridgeman & Wendler, 1991; College Board, 2008; NACAC, 2008; Wainer & Steinberg, 1992). Studies conducted by the College Board affirm the effect of stereotype threat on females’ mathematical achievement (College Board, 1998; GRE Board, 1999) and the majority of the gender gap on the SAT quantitative section (boys outscore girls by approximately one third of a standard deviation) has been attributed to stereotype threat (Walton & Spencer, 2009).

Thus, the general underperformance by females on these instruments, resulting from stereotype threat, leads to inequities in terms of access to post-secondary opportunities. In particular, relatively low and unrepresentative scores on high stakes, standardized mathematics exams can serve as a roadblock to women interested in pursuing careers in the STEM fields, where females are currently and historically underrepresented. Mathematics educators at all levels and college officials need not only to be made aware of these inequities, but also what can be done to level the playing field.

TRANSFORMING MATHEMATICS EDUCATION – APPLYING NEW IDEAS OR COMMODIFYING CULTURAL KNOWLEDGE?

Gale L. Russell
University of Saskatchewan
gale.russell@usask.ca

Egan J. Chernoff
University of Saskatchewan
egan.chernoff@usask.ca

In Saskatchewan, the renewal of mathematics education has two major initiatives to contend with: the incorporation of transformative teaching and learning strategies, and the infusion of First Nations and Métis content, perspectives and ways of knowing. Playing leading roles in the development and implementation of Saskatchewan's renewed curricula, we have struggled with the enormity of these changes and their effective implementation. This has led us to reflect upon the traditional Western Paradigm as it relates to mathematics education, and to consider the importance and role of other paradigms, in particular, an Indigenous paradigm to our work. In doing so, however, we have come to question the actual origins of the foundations to the current trends in transforming mathematics education, and whether the acknowledgement of non-Western knowledges and perspectives is not due in this regard.

In Saskatchewan, as is happening in numerous places throughout North America and the world, mathematics curricula and resources are being rewritten, renewed, and transformed to address the most current findings in mathematics education research. This most recent renewal process for Saskatchewan, as a member jurisdiction of the Western and Northern Canadian Protocol (WNCP), began with the reflecting upon and revising of the original Western and Canadian Protocol (the predecessor of the WNCP) Common Curriculum Frameworks. Representatives of the WNCP jurisdictions met regularly in order to make "optimum use of the limited resources" (WNCP, 2000) of the individual jurisdictions, resulting in the completion of the *Common Curriculum Framework* (CCF) *for K-9 Mathematics* (WNCP, 2006) and *Common Curriculum Framework for 10-12 Mathematics* (WNCP, 2008). Among numerous other sources of research, the National Council of Teachers of Mathematics' *Principles and Standards for School Mathematics* (2000) was foundational to the renewal process.

There were, however, some issues related to mathematics education, such as assessment and time allotments for courses, were, through consensus, left out of the renewal process and frameworks. From the onset, the infusion of First Nations and Métis (FNM) content, perspectives, and ways of knowing was believed by at least one member WNCP jurisdiction to be too contentious to reach consensus, resulting in no attempt being made. The compromise, a brief description of the learning styles of Aboriginal students, was included in the introduction to the CCFs. In Saskatchewan, the number of self-declared FNM students in provincial schools has been steadily increasing (Saskatchewan Ministry of Education, 2010, p. 52, 53). As well, these numbers do not reflect the students within the Federally controlled Reservation schools in Saskatchewan, who, for the most part, also follow Saskatchewan's curricula. These numbers, in and of themselves are by no means worrisome, but when one considers that self-declared FNM students are consistently scoring below non-FNM students by as much as 18.6% in grade 10 mathematics (Saskatchewan Ministry of Education, 2010, p. 49), the seriousness of this situation becomes much clearer.

In the process of "Saskatchewanizing' the WNCP CCF's, it was decided that the outcomes and indicators of the CCF, and not just the upfront matter of the curricula documents, needed to be

written to reflect teaching strategies that are supported by the Constructivist Learning Theory and to support the infusion of FNM content, perspectives and ways of knowing. Throughout the writing process, and the accompanying research and deliberations (with a fair share of disputes), however, the realization of the complexity of the situation emerged. Not only did the curriculum writers need to find ways to address the two initiatives within outcomes and indicators, but they also began to worry about how such major changes were to be accepted and enacted the field.
But are these two sites of debate, research and action in mathematics education - the transformation of mathematics teaching and learning and the infusion of FNM content, perspectives, and ways of knowing - really distinct phenomena? In this research paper, we will present arguments and examples to support the notion that transformative educational strategies being proposed and implemented today are in fact the implementation of an Indigenous paradigm onto the realm of mathematics education.
To set this stage for this discussion, we need to consider not only Constructivist Learning Theory, but also the fields of Ethnomathematics and Multicultural Education. The following literature review provides a brief introduction to these areas.

Literature Review

This literature review is divided into two sections. The first, on Constructivist Learning Theory speaks to the current research that has informed both the WNCP CCFs (WNCP, 2006; WNCP, 2008) and Saskatchewan's Renewed curriculum documents (e.g., Saskatchewan Ministry of Education, 2009). The second part of the literature review considers the fields of Ethnomathematics and Multicultural Education that have helped to infuse Saskatchewan's mathematics curricula with FNM content, perspectives and ways of knowing.

Constructivist Learning Theory

Constructivist Learning Theory emerged from the work of two researchers, working separately and unknown to each other: Jean Piaget and Lev Vygotsky. Although the two researchers varied in how they believed children moved from one stage of learning to another, both based their work on the idea that, as humans we generate our own knowledge through the interaction of our experiences and ideas.
In Vygotsky's work, the role of the more knowledgeable other, someone other than the learner who helps in the scaffolding of the learning to move the learner through and beyond his or her current zone of proximal development, is key to knowledge development. Thus, social interactions, and especially play in the early years, are seen as important tools for the learner. It is through these interactions that the learner explores new contexts and ideas, being guided by the knowledge and experiences of not only themselves, but also of those around them. Vygotsky proposed a variety of stages of development within learners, according to different types of contexts such as the development of tools and communication, each of which the learner negotiated and moved through at a rate that was supported by their experiences and social interactions (Vygotsky, 1962; Vygotsky, 1978).
Piaget, proposed that learners go through developmental stages (sensory-motor, pre-operational, concrete operational, and formal operational), however; in his work, Piaget's focus was on the cognitive, and not the social. Piaget believed that all learners move through these stages at roughly the same ages, and in the case of the formal operational stage, many people would never reach it. Piaget argued that the learners construct their own knowledge through interactions between their experiences and their ideas, within the constraint of their developmental stages. As learners interact with their environment, Piaget asserted that they had to go through process

of accommodation and assimilation to make new experiences and new ideas “fit” into their knowledge schemata. (Piaget, 1970; Gallagher & Reid, 1980).

Out of these ideas of social and cognitive constructivism, teaching and learning strategies for supporting the learner as they construct new knowledge have emerged. These strategies vary from broad spectrum approaches to learning, such as inquiry and problem solving, to more specific methods, such as the use of children’s literature, and multiple representations, that support teachers and students in engaging in the more broad spectrum approaches.

Ethnomathematics and Multicultural Education

The notion of a field of study of mathematics in other cultures has existed since at least the late 1890s (for examples, see Taylor, 1874; Smith, 1923, or Struik, 1948), but in the 1980s, the field of Ethnomathematics, influenced by the groundbreaking work of Ubiratan D’Ambrosio, emerged. D’Ambrosio (1997) reflects “Not much has been done in ethnomathematics, perhaps because people believe in the universality of mathematics” (p. 14). Ethnomathematicians, however, continue to provide evidence of the cultural biases in the mathematics within North American schools. Despite Kline’s claim that the plant of mathematics remained “dormant for a thousand years” (as cited in Powell & Frankenstein, 1997, p. 52), mathematics was alive and expanding in those parts of the world that were beyond the grip of the Dark Ages that encompassed much of the European world. Ethnomathematics as a field has exposed the fact that there is not one mathematics, not one way to think mathematically, and not one way to do mathematics. It should be noted that Ethnomathematics does not, as a whole, question the role that Western mathematics (that which is currently taught in North American society) plays in the dispositions of modern society, but it does question the claim of singularity and absolute authority that mathematics has been afforded. By recognizing and valuing the mathematics of other cultures and societies, past and present, Ethnomathematics is expanding the world of possibilities for mathematics and mathematics education.

Banks and Banks (1995) define Multicultural Education as

a field of study and an emerging discipline whose major aim is to create equal educational opportunities for students from diverse racial, ethnic, social-class, and cultural groups. One of its important goals is to help all students to acquire the knowledge, attitudes, and skills needed to function effectively in a pluralistic democratic society and to interact, negotiate, and communicate with peoples from diverse groups in order to create a civic and moral community that works for the common good (p. xi).

In order to facilitate the creation of these equal educational opportunities for students, Banks (2002) identified four different approaches taken in curriculum writing and reform: contributions, additive, transformative, and decision-making and social action. In the contributions approach, ethic heroes, holidays, and celebrations are added into the curriculum on certain days, but set aside, or presented as distinct from, the rest of the curriculum. When curriculum writers include content, themes, or perspectives from certain ethnic groups, but do not change the actual structure or purposes of the overall curriculum, the approach being used is called additive and can often be identified by the addition of a book by an ethnic author or the inclusion of an additional, ethnicity-based, unit. When a curriculum’s basic assumptions of a singular point of view and perspective is changed to embrace students’ engagement with content and issues through multiple ethnic perspectives, the transformative approach is being applied. Finally, the decision-making and social action approach to curricula builds upon the transformative approach by requiring the students to make decisions and engage in social action.

Reflections from a Saskatchewan Curriculum Renewal Perspective

In the renewal of the Mathematics curricula in Saskatchewan, the Constructivist Learning Theory played a major role in the wording of outcomes and indicators, as well as in the writing of upfront matter regarding the teaching and learning of mathematics within which those outcomes and indicators are couched. With respect to the infusion of FNM content, perspectives, and ways of knowing, Ethnomathematics provided a sense of the breadth of possibility and its importance, while the theory of Multicultural Education encouraged and provided support for teachers to step away from the contributions and addition approaches used in past curricula to a more transformative approach. This approach is supported by the inclusion of a new goal for K-12 mathematics education in Saskatchewan, that of understanding mathematics as a human endeavor: "Through their learning of K-12 Mathematics, students should **develop an understanding of mathematics as a way of knowing the world that all humans are capable of with respect to their personal experiences and needs**" (Saskatchewan Ministry of Education, 2009), which opens up the classroom to students' sharing and valuing of different personal and cultural perspectives and ways of knowing mathematics. Through their learning of all the mathematics outcomes, it is a curricular expectation that students will achieve this goal.

Theoretical Framework

All of the research done for the renewal of both the CCF and the Saskatchewan curricula did not shed light, or even hope, on the ever-looming question of "how will Saskatchewan's teachers manage all these changes – effective incorporation of new teaching and learning strategies and the infusion of FNM content, perspectives, and ways of knowing. Throughout the renewal and implementation process, the notion that if one effectively incorporated the new teaching and learning strategies that the FNM component would or could happen was in the air, but justification for such a claim was nowhere to be found. The question that then arose was, perhaps it is because the two ideas (pedagogical change and FNM infusion) are being housed (unnecessarily?) in two different paradigms, or within a single, non-Western paradigm.

Consider first, the paradigm from which the new teaching and learning strategies have been emerging – that of the Western or Eurocentric world. This paradigm has its own "ontological, epistemological, sociological, and ideological way of thinking and being" (Kovach, 2009, p. 21) that can be distinguished from other paradigms, such as Eastern or Indigenous paradigms. Examples of the many characteristics attributed to the traditional Western paradigm include: claim to holding a monopoly on knowledge, the existence of one true or right answer, a society of specialists, scientific knowledge being based solely upon measurable attributes, reliance upon linearity, and the necessity of objectivity (Kovach, 2009; Little Bear, 2000; Meyer, 2003). This underlying paradigm makes the valuing and incorporation of FNM perspectives, content, and ways of knowing into education difficult as such action would call into question many of the fundamental principles assumed within society. How can there be multiple ways of knowing or perspectives if one believes there is only one true answer; and what happens to objectivity when one allows for multiple interpretations and understanding?

Although there is no one FNM or Indigenous paradigm, as each Indigenous group has fundamental differences from each other (Kovach, 2009; Little Bear, 2000), there are common characteristics across Indigenous groups that allow for the presentation of an overarching and broad Indigenous paradigm. An Indigenous paradigm is one that values wholeness with focus being on the group rather than the individual, on interdependence rather than independence; it values relationships, not just between people, but with all of creation; it values reciprocity; it values diversity within the group; and it values the place where knowledge is constructed and lives (Ermine, 1995; Hogan, 2000; Kovach, 2009; Little Bear, 2000; Meyer, 2003; Youngblood Henderson, 2000). Thus, an Indigenous paradigm invites varying perspectives and ways of knowing; it considers not only the impact of actions and beliefs on individuals, but on all people and on the world around them; and it seeks not only to gain, but to give back as well.

Are there benefits to considering the seemingly disparate sites of mathematics curriculum renewal – new teaching and learning strategies and the infusion of FNM content, perspectives and ways of knowing – through the non-Western lens of an Indigenous paradigm? The analyses from this perspective, as well as from the perspective of the traditional Western paradigm (which follow) will not only reveal the benefit of such a consideration, but also call into question the origins of the current transformations to mathematics education.

Analysis

In our analysis, we consider the question of which paradigm – traditional Western or Indigenous – best accommodates the changes to mathematics education that are supported by current Western research. To do so, we examine both initiatives (the new teaching and learning strategies and the infusion of FNM content, perspectives and ways of knowing) in light of the characteristics of each paradigm to determine whether one paradigm better aligns with where we are trying to go with mathematics education.

The Traditional Western Paradigm

Being from a world dominated by the traditional Western paradigm, we begin by considering how the initiatives of incorporating new teaching and learning strategies and the infusion of FNM content, perspectives and ways of knowing align themselves within the traditional Western paradigm. Within this paradigm, the notion of infusing content, perspectives and ways of knowing that are not inherently part of the traditional Western paradigm, which is the case for FNM knowledge, is in contradiction to the paradigmatic belief that the Western world holds a monopoly on knowledge. Acceptance and action upon this initiative within the traditional Western paradigm would be tantamount to admitting that there is some knowledge and some ways of knowing that do not originate within Western society. Moreover, FNM perspectives and ways of knowing value relationships and diversity, giving the resulting knowledge both subjective and objective attributes which also contradicts the traditional Western paradigm.

What of the new teaching and learning strategies that are emerging from ongoing Western research into mathematics education? How well does Constructivist Learning Theory fit into the traditional Western paradigm? At first glance and at the broadest level possible, the theory and the traditional Western paradigm would seem to fit. Both Vygotsky's and Piaget's theories assume a linear nature to learning, and the evidence for the theories is based upon scientific measurement and the application of objectivity. It is in the application of these theories, however, that a divergence from the traditional Western paradigm begins to occur. Inquiry and problem-based learning, although frequently taken to consensus, encourage students to consider alternative perspectives and representations, and the goal is no longer just the final 'truth', but also the processes and relationships developed along the way. Moreover, the use of literature in mathematics teaching and learning brings forward context and subjectivity, both of which are foreign to the Western paradigm of true mathematical knowledge. Likewise, strategies such as the use of multiple representations conflicts with the Western belief in one correct answer, and must ultimately give way to the penultimate symbolic mathematical form of representation. Thus, we contend that the traditional Western paradigm does not support the current transformative teaching and learning strategies proposed by mathematics education research.

An Indigenous Paradigm

We begin our analysis of recommendations for the transformation of mathematics education with respect to an Indigenous paradigm by considering the infusing of mathematics education with FNM content, perspectives and ways of knowing into mathematics curricula. In an Indigenous paradigm, the consideration of alternative perspectives and ways of knowing is a foundation rather than a contradiction to one's beliefs. An Indigenous paradigm not only recognizes, but welcomes new content and perspectives as a way of understanding the continuous flux of life (Kovach 2009; Little Bear, 2000; Meyer, 2003), making the infusion of FNM content, perspectives, and ways of knowing not only a possibility, but recognizing it as a necessity for the creation and application of knowledge. In an Indigenous paradigm, knowledge is grounded in place, and the infusion of FNM content into mathematics education is also about understanding the relationship between place and knowledge. As is probably not a surprise, the infusion of FNM content, perspectives and ways of knowing into mathematics education is one that is not only supported, but also endorsed by an Indigenous paradigm.

As noted previously, Constructivist Learning Theory, whether it be Piaget's cognitive development theory or Vygotsky's social development theory, does not, at the outset, require an Indigenous paradigm to fit into mathematics education; however, when one begins to consider the application of these theories to the actual acts of teaching and learning there becomes a much stronger alignment with an Indigenous paradigm over the traditional Western paradigm. Our earlier analysis noted how this realignment with paradigms begins to be apparent with the introduction of inquiry and problem-based learning. Now consider strategies such as the incorporation of children's literature, integration of subjects, and the use of multiple forms of representation in communicating and exploring mathematical ideas.

For Indigenous peoples around the world, language and oral communication are essential to the creation and maintenance of their cultural identities and knowledges (Absolon & Willet, 2005; Battiste, 2000; Kovach, 2009; Leavitt, 1995; Meyer, 2003). Little Bear (2000) notes that within Indigenous cultures, and thus within an Indigenous paradigm, "Storytelling is a very important part of the educational process. It is through stories that customs and values are taught and shared" (p. 81). The increasing use of children's literature books in mathematics instruction and learning in Western classrooms shares in these same paradigmatic beliefs about storytelling.

In an Indigenous paradigm, holistic views of the world and of knowledge are foundational - knowledge is not categorized into distinct disciplines; rather, it exists within the context of life experiences in a particular place (Ermine, 1995; Little Bear, 2000). Unlike the traditional Western paradigm, based in the Eurocentric belief that all knowledge falls into dualities and differences, an Indigenous paradigm does not try to separate out component parts of an experience, rather it encourages the valuing of the whole. In this way, the movement towards teaching and learning through the integration of different Western subject areas, is also in much closer alignment with an Indigenous paradigm than a Western one.

Likewise, the encouragement of students and teachers to learn, incorporate, and relate between multiple forms of representation, including oral communication, pictures, and concrete objects, and not just using abstract symbols, also pulls the teaching and learning of mathematics from the traditional Western paradigm and towards an Indigenous one. The openness of these teaching and learning strategies to alternative strategies and ways of knowing about mathematical ideas contradicts the Western need for objectivity, linearity, and a single, correct answer. These same features, however, bring such teaching and learning strategies in direct alignment with an

Indigenous paradigm by inviting students and teachers to openly consider and value alternative ways of knowing and understanding, and to celebrate diversity in thinking.

Discussion

Our analysis of the two initiatives of change facing mathematics education within the province of Saskatchewan, and undoubtedly elsewhere in the world, that of the infusion of FNM content, perspectives and ways of knowing and the introduction of new teaching and learning strategies, demonstrates how at least a significant portion of the transformations occurring in mathematics education are not supported by the traditional Western paradigm within which school mathematics currently sits. Instead, there is much evidence to suggest that an Indigenous paradigm might be a more appropriate choice for the enactment of these initiatives. One could argue that the new teaching and learning strategies aimed at mathematics education are as much a consequence of thinking within an Indigenous paradigm as they are aligning with the traditional Western paradigm. It is in this realization that the complexity of the changes being called for within mathematics education may find some resolution and simplification; that is, perhaps what we need to do in mathematics education is to focus on changing our Western paradigm to that of a more Indigenous paradigm, and thereby the educational changes we desire will become natural consequences of our beliefs rather than being at odds with them.

Perhaps, also, our analysis is an indication that the traditional Western paradigmatic view of mathematics education is already moving towards a more Indigenous paradigm. If so, perhaps we need to consider the words of Youngblood Henderson (2000) "In the Eurocentric construct of three-dimensional time, whoever masters the present moulds the past" (p. 65), and Smith's (2000) concern that the traditional Western paradigm seems to see the world as a "huge supermarket in which knowledge can be packaged up to be bought and sold…[without considering] the intellectual cultural property rights" (p. 218) of Indigenous peoples. If we are to let go of only some aspects of the traditional Western paradigm to let these transformations easily enter the world of Western mathematics education, then do we not need to be careful that credit is given where credit is due? Should we not be careful to avoid laying claim to the present findings by ignoring the past knowledge of others; should we not be taking care to not package someone else's wisdom under our own label? As much of the world struggles with the devastating impacts of colonization and other forms of intolerance and unsubstantiated assertion of power, do we not as mathematics educators and mathematics education researchers have an important role to play in this struggle? We believe that this convergence between an Indigenous paradigm and the transformation of mathematics education is not a mere coincidence, but the gradual evolution of parts of Western thinking into more Indigenous ways of knowing, and although the application of this thinking may be taking on forms different from those historically found within an Indigenous paradigm, the foundations for such thinking, which are also foundations of an Indigenous paradigm, should be recognized and honoured.

"I SEE ZEROS": DEVELOPMENT OF PATTERN IDENTIFICATION SKILLS IN STUDENTS WITH LANGUAGE DELAYS

Helen Thouless
University of Washington
hthoules@u.washington.edu

Most research on teaching mathematics to students with learning disabilities has focused on explicit procedural instruction or rote learning. Instead, this study focused on what two first grade boys with language delays learned about patterns from Choral Counting, an instructional activity designed to encourage communication of mathematical ideas. This focus led to the research question: What do elementary students with language delays learn about identifying patterns as they engage in Choral Counting? Video interaction analysis taking a sociocultural perspective enabled me to investigate the resources that they use to express their mathematical ideas. Findings indicated that Choral Counting was a valuable instructional activity for these students: they grew in their abilities to count by various numbers, to identify patterns, to express their mathematical ideas, and to use nonverbal communication methods to clarify their meaning.

Introduction

Most research on teaching mathematics to students with learning disabilities has focused on explicit procedural instruction or rote learning (Miller, Butler, and Lee, 1998). The problems are broken down into their component parts, and the students are expected to master the components on their way to solving the problem. This type of instruction is time-efficient, makes overt the covert thinking strategies that support mathematical problem-solving, and does not depend on students' ability to intuit concepts from experience, or to work in a self-directed manner (Karp and Voltz, 2000, p. 208). Procedural instruction, however, also has its disadvantages. The students become dependent on the teacher's assistance, and there is limited opportunity for in-depth understanding, which leads to limited retention, generalization, and ability to apply the information (Karp and Voltz, 2000, p. 208). Because students may develop little conceptual understanding of the procedures, the procedures are also liable to be error prone (Woodward and Montague, 2002, p. 95).

Given the disadvantages of overemphasizing explicit procedural instruction and rote learning, research is needed on other instructional methods for students with learning disabilities. In particular, teaching through mathematical discussions has potential and is worth studying (Woodward and Montague, 2002, p. 97). In this study I focus on what students with language delays can learn by engaging in a particular instructional activity that encourages the communication of mathematical ideas. Specifically, I focus on what students with language delays learn about patterns when they engage in the instructional activity of Choral Counting.

Choral Counting is a 10-15 minute warm-up. Prior to the count, the teacher has thought about where to start and end the count, what to count by, whether to count forwards or backwards, and how to record the count. The class counts together out loud while the teacher records the count. At a strategic point, the teacher stops the count and encourages the class to discuss numerical patterns that students notice. During Choral Counting students practice counting, identify patterns, and engage in mathematical reasoning as they predict numbers that will occur in the count (http://sitemaker.umich.edu/ltp/home).

This study is an example of a self-study, as I was the resource teacher of the students being studied and was motivated by my own experiences. I tried to teach mathematics through direct instruction for a couple of years and was dissatisfied with the limited progress that my students were making in mathematics. While my students were able to do simple sums, they fared poorly on the state test that required them to solve novel problems and give explanations for how they had solved the problems. Consequently I wanted to experiment with another way to teach mathematics.

In my university, prospective teachers were being taught five routine instructional activities that encouraged students to interact with one another and communicate mathematical ideas and develop fluency with mathematical concepts and procedures (Lampert *et al*, 2010). Although I adopted most of these routines in my Resource Room class, in this paper I focus on one routine: Choral Counting. This decision led me to my research question: What do elementary students with language delays learn about identifying patterns as they engage in Choral Counting?

In the process of investigating this question I present the progression of numerical pattern identification of two first grade students with language delays over a three-month period. I present how they first thought of patterns and how they changed their conceptions of patterns as the months progressed. I present the differences between these two students in the types of patterns they tended to observe. I also present how they communicated their understandings of the mathematics. This paper expands current studies of mathematics learning because it examines a group of students who are rarely asked to communicate their mathematical ideas.

Conceptual Framework

A sociocultural perspective guides the view of learning in this study. From this perspective, learning is transformation of participation in a “skilled, valued sociocultural activity” (Rogoff, 1990, p. 39) and takes place within a social context with experts and novices engaging together in the activity. Participants have relationships with each other that mediate the individuals’ learning and this mediation occurs through discourse—communication that occurs through words, gestures, and actions (Cazden, 2001).

Moschkovich (2007) argued for using a sociocultural framework for understanding the resources that bilingual students use when communicating mathematically. These students struggled to find the words to describe the mathematical concepts that they had, and had Moschkovich looked at their words alone she would have concluded that they were not understanding the mathematical concepts. Instead she looked at the whole social context and realized that these students were using gestures, objects, artifacts, and their first language to express their mathematical ideas. When Moschkovich studied bilingual students’ participation in mathematics lessons from a sociocultural perspective, she could see all of the resources that they were using to construct meaning.

Like Moschkovich, I have chosen a sociocultural perspective to investigate the resources that students with language delays use when communicating mathematically, because this perspective allows me to examine their strengths. Students with language delays struggle to express their ideas verbally, but an interaction analysis taking a sociocultural perspective enables me to investigate other resources that they use to express their mathematical ideas. Students may use gestures and artifacts to communicate mathematical ideas that they are unable to express verbally. Such analyses afford a fuller estimation of the ability of students with language delays to do mathematics than a limited examination of students' verbal functioning.

Students with special needs do not often get the chance to talk about mathematics because "such children are assumed not to be linguistically prepared to participate in reform-based practices" (Hufferd-Ackles, Fuson, & Sherin, 2004, p. 82). However, students with language delays may actually need more opportunities to participate in mathematics discussions than typically developing students. They may need more practice communicating mathematically, just as they need more practice communicating in other modes. This means that mathematics lessons should be designed to support students' language goals as well as the mathematical content. These language goals will be more readily addressed with mathematical discussions than by direct instruction.

Methods

Subjects

The participants in this study were two first grade students receiving Special Education Resource Room services at Uhuru School (all names are pseudonyms) in the 2008-2009 school year. Their school was in an urban area in the Northwest U.S.A.

Martin (M) and Ali (A) were both members of my primary Resource Room mathematics group. They both had language delays (LD), with expressive language skills more typical of a 4 year-old than the 6 years-old they actually were. They tended to use 2-3 word sentences, often missing out grammatical features of the sentences such as verbs. Martin spoke more clearly than Ali, who tended to skip some of the consonants in words, which made his speech hard to understand. Despite these language delays, they both spent the majority of their school day in a general education first grade classroom and were making progress in the general education curriculum.

I chose to study Martin and Ali because at the beginning of the study they both had Individual Education Plan (IEP) goals related to counting, so the Choral Counting routine was directly related to their IEP goals. In September 2008, they both had mathematics goals on their IEPs that referred to rote-counting, one-to-one counting of objects, and recognizing numerals. Although these students had similar mathematics goals, there were differences in their goals. Martin's goals involved higher numbers than Ali's—reflecting their relative skill levels. In September, Ali still had difficulties counting above 12 by ones, whereas Martin could count to 100 by ones. Ali could reliably count ten objects, whereas Martin could count up to thirty objects. Ali recognized 5 numerals reliably--1, 2, 3, 8, 10—at a stage when Martin could recognize the majority of the numbers up to 50.

Martin and Ali had different home languages. Martin's family spoke English in the home. Ali's family spoke Somali at home, although his mother reported that he was more comfortable speaking English than Somali. Ali was receiving ELL services as well as Special Education services.

Procedures

In my primary mathematics class we engaged in Choral Counting approximately weekly from November 2008, until March 2009. We then continued to engage in Choral Counts once or twice a month from April 2009, until June 2009.

First, I chose a counting sequence for the students. These counting sequences were either by twos, fives, tens, ones, or backwards by ones. When counting by ones, the count started from a number in the low double digits because the students were very familiar with counting by ones from one. These counting sequences were selected because they are the ones that the state has identified as the essential counting sequences for first grade students. The *Washington k-12 Mathematics Standards* (2008) state that first grade students should be able to, “Count by ones forward and backward from 1 to 120, starting at any number, and count by twos, fives, and tens to 100” (p. 11).

Once I had introduced the counting sequence to the students, we would start counting together and I would write the numbers as we said them, having chosen ahead of time how to arrange the count on the board so that patterns would be discernable. After three or more rows or columns of numbers were written, I would stop the count and ask the students what patterns they were seeing. I would represent those patterns on the count and ask the students to predict the next number in the pattern (Kazemi and Hintz, pp. 5-9).

Data Collection & Analysis

The data for this study was collected by videotaping thirteen of my Choral Count lessons from November 2008 until June 2009. After watching all the videotapes, I chose to analyze three episodes that showed how Ali and Martin changed their understandings of what a pattern consisted of across the course of the study. I analyzed a count from mid-December, which was towards the beginning of my study when the students still believed that patterns consisted of shapes. The next count I analyzed came from mid-January, where both boys showed an understanding and recognition of patterns in the numbers. The final count that I analyzed came from early March, where Martin recognized a more sophisticated pattern than he had previously recognized. The December count was a count by 2s, the January count was a count by 10s, and the March count was a count by 5s.

I then transcribed the three episodes, just focusing on the parts of the counts where Martin and Ali were talking about the patterns that they had observed. I transcribed these episodes using conventions commonly used in interaction analysis (Schegloff, 1997). I wanted to pay close attention to both the words and actions of the discussion participants, because the words, hesitations, gestures, and the physical location of the participants were important clues to what the students understood about patterns and how confident they were about their answers.

I then repeatedly reviewed the video alongside the transcript and coded for instances of student learning and understandings, and students’ interactions with the artifacts. I annotated the transcript with notes about how the students were currently thinking about patterns, their positioning in relationship to the numbers on the board, and their interactions with the numbers.

Results

Growth in Pattern Identification

In this section I show a sequence for the growth in the types of patterns recognized: (1) shapes as patterns; (2) patterns where the digits stay the same; (3) digits that change systematically; and, 4) digits that show repetition while changing systematically. I also show how the boys established a norm for communicating about the numbers.

Shapes as Patterns

In the December episode, Martin thought that when I asked him to tell me about a pattern he saw, he was expected to respond with the name of a shape:

T: What’s a pattern you see Martin?

M: Umm. A square right there.

This was a reasonable answer if I had been looking for a shape answer. The count at that moment was a five by six grid plus two extra numbers (See Figure 1).

Figure 1: *Count by 2s, December*

2	4	6	8	10
12	14	16	18	20
22	24	26	28	30
32	34	36	38	40
42	44	46	48	50
52	54	56	58	60
62	64			

Martin's pattern
Ali's pattern

In Martin's world, patterns were shapes so even though there were no obvious other shapes to be seen in the count, he continued to look for shapes:

M: Ooh! A triangle

T: I don't see a triangle

M: Circle

A: I see it

M: Rectangle

These answers were less reasonable given the count, but emphasized his conviction that questions about patterns had a shape as an answer.

Patterns where Numbers Stay the Same

This was the second time that I had introduced these students to the idea of looking for patterns in the numbers, but Martin's responses made it clear that he was still focused on looking for shape patterns. So I reminded the students about the previous lesson where I had modeled finding a pattern in the numbers, "I'm seeing patterns in the numbers. Like last time we saw patterns in the numbers, Jose and I?"

Ali was the first to give me a number response, but it is unclear from his initial response whether he was just saying a number or he had seen a pattern,

A: Uh. I see fourteen?

T: Fourteen? Yeah? [Points to the number 14 on the board] What about fourteen?

A: Uh. Ecos e ba one an four {Because it has a one and a four.}

I decided to take his answer and emphasize a pattern that he could be seeing that involved 14,

T: What's the same about the one's place [Drops finger down along the 4s in the ones place] all down here? What's the same? [Moves finger up and down along the 4s.]

M: The four

A: four [Says number at the same time as M.]

At this point both boys were focused on looking at the numbers and they simultaneously responded that the 4s stayed the same in that column (See Figure 1).

Martin was able to take the idea of looking for digits that stayed the same and communicate a new pattern independently,

M: I see um zeroes

T: Where. Tell me where. [Martin gets up.] Tell me.

M: Uhhh. Right here [MF goes to the board and points to the zeroes in the final column. As he counts he points to each number.] Ten. Twenty. Thirty. Forty. Fifty.

He now saw that the final column always had a zero at the end (See Figure 1). In a minute and a half, Martin went from seeing patterns as always being about shapes to being able to communicate a pattern that he saw in the numbers.

In this interaction Martin initiated a norm for communicating about the numbers. I asked him to tell me which numbers he was talking about and instead he chose to go to the board and show me the numbers. This innovation was taken up by the other student and by January it had become a norm for the students to come to the board when they were trying to explain which numbers they were talking about.

In December it was not clear whether Ali really understood what it meant to look for a pattern in the numbers, but by the January episode he showed that he was looking for similarities between the numbers and he communicated this similarity. He saw that there was always a 10 in the numbers in the first row, 10, 110, 210 (See Figure 2).

A: Uh, a tens [comes to board, points to the first 10] got a number one zero, one one zero [points to 110.]

T: OK. So you've seen ten, ten, ten, ten. [T underlines 10 and the ten in 110, in 210, and 310. A walks back to his desk.]

In the January episode, Ali showed growth in pattern recognition from December. He now knew that he was meant to look for patterns in the numbers. He communicated that he saw a similarity between the numbers in the first row. The words that he said, "Uh, a tens…got a number one zero, one one zero," could have been easily misconstrued but because he came up to the board and pointed at the relevant numbers, I knew exactly which tens he was talking about. This growth in his communication skills allowed me to comprehend the pattern that he was indicating. The pattern that he saw in January was more sophisticated than the one he saw in December because this one involved two digits that stayed the same rather than just one digit.

Figure 2: *Count by 10s, January*

10	110	210	310	
20	120	220	320	
30	130	230	330	
40	140	240		
50	150	250		
60	160	260		
70	170	270		
80	180	280		
90	190	290		Martin's pattern
100	200	300		Ali's pattern

Patterns where Numbers Change Systematically

In the January episode, Martin also shows that he is now focusing on patterns in the numbers rather than shapes. He shows a pattern in the tens place where the tens place systematically changes by one (See Figure 2),

M: I see 2, 3, 4, 5, 6, 7, 8, 9, [points to each number in the tens column as he says it.] te...

A: Ten

M: Ten

As I did not ask him to continue his pattern in the second column, it is unclear whether he saw the pattern in the tens place as a repeating pattern: 123456789123456789123456789; or as a pattern that incorporates the hundreds place into the pattern he was seeing in the tens: 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17. I suspect that this latter pattern is the way that he saw his pattern because of his use of the word "ten". In later counts, he consistently used this latter pattern, which strengthens my conviction that this is how he was seeing the pattern in this episode. However, his hesitation at "te…" suggests that he was unsure at this point and was not sure how his pattern continued.

In January, Martin shows that his understanding of patterns has evolved from seeing patterns as shapes, and even from looking for similarities between numbers. He is now looking for patterns in how numbers change systematically.

Patterns with Repetition within Systematic Change

In March, Martin identifies a new pattern. He sees a pattern of the form: 11223344, etc. (See Figure 3),

M: 1, 1, 2, 2, 3, 3, 4, 4, 5, 5 [M points to every number in the tens place as he comes to it.]
T: Ok. Let...let me. So in the tens place it goes 1, 1. Then it goes 2, 2 [Circles the numbers as she says them.]
This pattern shows that Martin has grown in his understanding of what a pattern can be. He can now see repetition within systematic growth.

Figure 3: *Count by 5s, March*.

5	10	15	20	25	30	35	40	45	50
55	60	65	70	75	80	85	90	95	100
105	110	115	120	125	130	135	140	145	150
155	160	165	170	175	180	185	190	195	200
205	210	215	220	225	230	235	240	245	250
255	260	265	270	275	280	285	290	295	300
305	310								

Martin's pattern

When Martin got to the number 95, he hesitated and so I asked him what came next:
T: Wha...What happens here?
M: Zero.
T: So does it go back to zero or does it go on to ten.
M: Goes on to ten right here. [Pointing to 10 in 100.]
T: OK. [Circles the number he indicates.]
M: Don't circle that one [Points to 0 in ones place.]
T: Ok. Ten
M: Ten [Points to number.]
T: Mm
M: Eleven [Points at the number.]
T: Eleven
M: Eleven [Points at the number.] Twelve...[Points towards number but does not touch it.] Twelve...Thirteen, thirteen, fourteen, fourteen, fifteen, fifteen, sixteen, sixteen, seventeen, seventeen, eighteen

Martin's hesitation after 95 showed that he was not sure how his pattern progressed once the numbers were in the hundreds, but he eventually decided that his pattern incorporated the hundreds place into the pattern he was seeing in the tens.

Discussion

Choral Counting was a valuable mathematical routine for these students with language delays. It helped them become more adept at counting by various numbers, including 3-digit numbers. Choral Counting was a useful routine to help these students with language delays grow in their ability to identify patterns—an important mathematical skill. It exposed them to the idea of using patterns as a way to help them skip count by various numbers. Choral Counting allowed the students to express their mathematical ideas and helped them become used to using nonverbal communication methods to clarify their verbal explanations. From a sociocultural perspective, these students learned these mathematical skills because they had the opportunity to engage in Choral Counting, so their ideas shaped and were shaped by their participation in the activity.

In three months, both students made growth in their ability to identify patterns. They moved from looking for shapes as patterns to looking for patterns in the numbers. Ali independently identified patterns where the digits stay the same. Martin could identify several different types of patterns in the numbers: digits that stay the same, digits that change systematically, and digits that show repetition while changing systematically. The routine of Choral Counting has encouraged these students to search for patterns in numbers, which is one of the major tasks of mathematicians.

These boys also showed growth in their communication skills over the course of the study. They both had difficulties communicating verbally due to their disabilities, but they found other ways to communicate what they were thinking. They established a norm that the student who had the floor would come up to the board to point at, and thus clarify, the numbers they were talking about.

One of the limitations of this study was that the two roles that I had in this study—teacher and researcher—were difficult to negotiate. Did I really see that evidence of understanding in the video? Or did I see evidence in some other part of the lesson that is not recorded and then read into the video evidence that is not there? Did I see some glimmer of understanding because I am their teacher and am invested in these children's lives, while an outside observer might not see the same evidence of understanding?

In future studies it would be interesting to compare the participation of students with language delays in activities that elicit their mathematical thinking, such as Choral Counting, with their participation in other activities that are typically found in mathematics lessons.

In future studies it would be interesting to work with groups of students with different disabilities. For which groups of students is Choral Counting a worthwhile activity?

NEGOTIATING PRAXIS FOR EQUITY IN MATHEMATICS EDUCATION: HOW PD SUPPORTS TEACHERS' DEVELOPING CONCEPTIONS

Anita A. Wager

awager@wisc.edu

Mary Q. Foote
Queens College-CUNY
mary.foote@qc.cuny.edu

This study contributes to a growing body of research considering professional development focused on both mathematics and equity. The study examined how lived experiences provide a foundation for ways teachers take up equity in their mathematics teaching practice. Constructs of praxis and figured worlds frame the study. The figured worlds of teachers participating in professional development were explored with a focus on how they contributed to where the teachers located praxis for equity in mathematics. Contributions were noted from the figured worlds the teachers inhabited both in and out of the professional development.

Attention to issues of equity and diversity within mathematics education is an area of growing interest. For some, this interest grows out of an effort to understand the gap in achievement between historically underserved students and their White, middle-class peers (Lubienski, 2008). For others, a focus on the achievement gap masks circumstances at the local level (e.g., access to courses and experienced teachers, procedurally-focused instruction) that significantly impact school performance (DiME, 2007; Gutiérrez, 2008; Martin, 2006). While there is a rich body of research on professional development (PD) that focuses on attending to student thinking in mathematics (Franke, et al., 2009; Kazemi & Franke, 2004; van Es & Sherin, 2010) and a separate but equally fertile body of literature on PD that address general issues in attending to diverse learners (Cochran-Smith & Lytle, 2001; Sleeter, 1997), literature that attends to both is emerging. In this paper we report on a study that contributes to this growing body of literature that considers PD focused on both mathematics and equity (See for example Civil, 2002; Crockett & Buckley, 2009; Foote, 2010; Weissglass, 1994).

Contributing to a lack of equity in schools, is a socio-cultural distance that has been noted between the majority of teachers, over 85% of whom are White and middle class (Howard, 1999), and the ever more diverse groups of students whom they teach. PD provides a vehicle for researchers to examine this gap in lived experiences between teacher and student (Foote, 2010). Such a PD program was designed to provide elementary school teachers with an opportunity to examine their mathematics classrooms with an explicit focus on equity.

Theoretical Perspectives

Research suggests that high quality professional development: (a) is situated in the work of teaching, (b) is focused on student thinking and learning, (c) supports professional learning communities, (d) is sustainable and credible, and (e) is research based and supported (Whitcomb, Borko, & Liston, 2009). The PD we studied not only incorporated all of these elements, but also incorporated another that we think needs more attention in the PD research - how teachers' experiences in figured worlds shape how they take up the goals of PD and where they locate the praxis that the PD intends to support.

Praxis

In discussing actions teachers either took or envisioned in an effort to achieve greater equity in mathematics learning we are referring to praxis. The term praxis regularly appears in the discourse on PD without being specifically defined. In our work we draw on the definition used in critical race theory (CRT), "the connection between theory and practical work aimed at transforming concrete social institutions" (Delgado & Stefancic, 2000, p. 591). This definition goes beyond the Aristotelian view of praxis that considers human activity as directed at a particular end with a goal of realizing something worthwhile (Carr, 1995) and incorporates Freire's (2007) view of action for transformation. In our use of the CRT perspective, the "goal of realizing something worthwhile" is more specifically defined as working toward achieving equity. Praxis is not the end itself nor a product but action that leads to the goal, the process of putting theoretical knowledge into practice. Potential sites for praxis that a teacher might target include the classroom, school, district, and society. These sites exist in a nested configuration of classrooms within schools, within districts, within society, although we do not intend to suggest a linear interaction. Additionally, we view society as incorporating but not limited to such things as families and communities.

Experiences in the Contexts of Figured Worlds

As suggested by Gutiérrez (2002), teachers' practices are not just limited to their knowledge, beliefs, and experiences, but are influenced by the context in which they teach. In addition to the teaching context, the context of PD (and other contexts outside of the school setting) influences teachers' views on changing their practice (Borko, 2004; Kazemi & Franke, 2004). Identity is developed through participation in and interaction with this complex matrix of communities (contexts) with which we engage throughout our lives (Holland, Lachiotte, Skinner, & Cains, 1998). Holland and colleagues argue that identity develops within what they call figured worlds. For them, identity is situated (or contextual) and socially dependent (or relational) and therefore cannot be appreciated apart from its social context. This notion of figured worlds and the movement of teachers among the various worlds they inhabit is a useful one for considering the development of their identities as mathematics teachers and understanding why they identify particular places as needing change. To understand all the contributions to identity or to develop a complete explanation of the development of any individuals' identity is well beyond the scope of this paper. We can, however, consider how particular lived experiences in the figured worlds they have and continue to inhabit may contribute to the ways in which teachers take up certain issues, in this case equity in mathematics.

From among the figured worlds that participants inhabit and because of their experiences within these worlds, they identify the space in which they hope to take action or believe that action is necessary; in other words, where praxis should be located. This leads us to question how teachers' experiences in different contexts influence how and where they locate praxis regarding equity and the teaching and learning of mathematics?

Methods

Background of the PD and Participants

A yearlong PD seminar was developed to support and study teachers as they considered issues of equity in their teaching of elementary mathematics. In considering ways to weave together discussions of equity and mathematics, the researchers drew on scholarship in algebraic thinking (Carpenter, Franke, & Levi, 2003), PD linking equity and mathematics (Weissglass, 1994), multicultural PD design (Sleeter, 1997), and multicultural education (Nieto, 2004). During each seminar session, teachers discussed one chapter from *Affirming Diversity* (Nieto, 2004) and observed one video text of third graders working on algebraic thinking problems. Between seminar meetings each teacher considered a target student in her classroom from the perspective of two lenses: (a) algebraic thinking, and (b) how issues of equity and diversity might be impacting that child's mathematics performance in the classroom.

The PD met once per month during the school year for a total of nine, two-hour meetings. Participants were randomly assigned to one of four subgroups that were purposefully maintained throughout the year in hopes that participants could build community with a smaller group of teachers, something that we believed might be an important consideration during difficult discussions that can arise when equity issues such as race and poverty are raised.

The participants in the PD were 18 elementary school teachers from a single school district in a moderately sized Midwestern city. Participants included 10 classroom teachers, one substitute, two ESL teachers, two math resource teachers, and three district resource staff. From among these participants, we identified one case study teacher from each of the subgroups. Because of space constraints, in this paper we will consider one of our case study participants, using her as an exemplar of how past experiences, current experiences, and the PD itself contributed to where she located praxis

Data Generation

In order to support teachers in positioning themselves in terms of their experiences and contextual positions and to develop a deeper understanding of who the teachers were and how they might engage with PD (Connelly & Clandinin, 1988), teachers wrote a mathematical and diversity autobiography. These autobiographies revealed prior experiences and beliefs regarding the teaching and learning of mathematics on one hand and issues of equity on the other. In order to capture the nature of the conversations within each group, all group discussions were audio recorded and later transcribed for analysis. Each month, teachers wrote reflections about their target student and their own experiences in their school setting. Through this use of both written and verbal perspectives, we were able to triangulate the data.

Data Analysis

There were two phases of data analysis. First we examined the small group discussions to develop an understanding of the group contexts. Second we developed trajectories of individual teachers around their engagement in the figured worlds that they had and currently do inhabit. In analyzing the small group discussions, we drew on grounded theory (Charmaz, 2005; Glazer & Strauss, 1967) to identify and develop an understanding of the group contexts as they emerged and influenced our participants. Members of the research team met regularly to discuss their impressions of the sessions as a whole and the small group discussions in particular. This sharing of impressions helped inform a general view of the small groups which was then further refined based on analysis of the transcripts. After identifying the overall orientation of the different groups, the data sources were analyzed to develop an understanding of the initial positioning and trajectories of the case study teachers. Autobiographies were read to gain insight into the experiences and figured worlds contributing to teachers' identities as they entered the PD. The transcripts for the monthly meeting of each group were read and re-read; emergent themes were noted. Teacher reflections for each month were read and coded as to whether the teacher discussed the Nieto (2004) text, the video text, her target student, or her teaching practice more generally. Using these data, narratives for each of the case study participants were developed independently by each of the authors and then compared. These narratives provided both background on the initial positioning of the case study teacher and insight into her trajectory.

Results: Case Study of Reflection on Praxis

We present our results by focusing on our participant Deb. We first discuss the influence of experiences in her figured worlds on the where she started her thinking in the PD. We then turn to considerations of the individual PD group to which Deb belonged. Finally, we discuss the influence of identity and group dynamics on how she developed and where she located praxis.

Deb

Deb had a middle-class, suburban upbringing, but taught in two large urban districts for 16 years before moving to her present school. She completed a traditional teacher education program in a large city and became a classroom teacher in a school that was 100% African American and all of whose student body (with the exception of three students) lived in nearby public housing. She was horrified by the conditions at the school and the treatment of the students. This fueled an early interest in producing large scale change; Deb recognized early on that major changes were required well beyond her classroom. Deb brought some of this zeal with her to teaching in another urban district, but after the events of September 11, 2001, reconsidered life in a large city and eventually moved to the smaller city where the study takes place. At the time of the study, Deb was a school-based mathematics resource teacher in a school that was experiencing a rapid shift in student demographics. It was her first year teaching in the school and she was frustrated with many of the other teachers in the school who she saw as wanting the new, more diverse students to assimilate before they could be taught. She saw her target student as marginalized by his classroom teacher who dismissed the knowledge he brought to school. Deb was very conscious of what she perceived as racist attitudes in her school and in her target student's classroom. She also likened the problems she read about in a chapter in *Affirming Diversity* (Nieto, 2004) to those she saw with district sponsored PD on racism. Although she was aware she had more experience than most of her colleagues in teaching children from diverse backgrounds, Deb was also conscious of jumping to conclusions about her colleagues.

Despite the fact that teachers had been randomly assigned to subgroups, four of the five teachers in Deb's group were resource teachers either for mathematics or English as a Second Language (ESL) and all had extensive multicultural experience. All these teachers considered themselves and each other to be strong multicultural educators. Feeling that they had already explored their own selves and responsibilities, they looked instead at their schools as sites where improvement was necessary. Because of this orientation, there was limited space within the group for interrogating individual views; they adopted a taken-as-shared orientation in which they agreed that teaching mathematics for understanding was an important pedagogical stance and that valuing children's out-of-school experiences was important to student success. Together they were empowered to criticize other teachers at their schools who they felt (a) did not share their orientation toward mathematical teaching and learning and (b) did not appreciate the funds of knowledge (e.g., linguistic and cultural) that diverse students were bringing to the classroom.

Deb joined her colleagues in agreeing about what other teachers did wrong. She used her journal to consider ways she could help others change. The low expectations teachers at her school had for her target student and others like him worried her, and although she judged the teachers' views of the students, Deb was also aware of her own judgmental stance, "Maybe I am the judgmental one who needs an attitude adjustment. I will watch myself." (Oct. reflection). Toward the middle of the year, as she continued to experience resistance from the classroom teacher of her target student to reconceptualizing the student's abilities, her viewpoint shifted away from working with that teacher. Instead, she began to intervene directly with the target student to support him academically. Yet, in another instance, toward end of the year Deb began to question how, in her position as mathematics resource teacher, she could support teacher development when her estimation of what was necessary for teacher development went beyond mathematics and included understanding students.

> How can we move teachers toward understanding of the concept of "mutual accommodation" and the mindset of "academic success with cultural integrity?" How can we help her to understand what accommodation means, and show her that it is [currently] her students who are unlike her who have doing the accommodating? Can this understanding be taught to a veteran teacher who up until a few years ago worked only with students from similar backgrounds to her own? (May reflection)

Deb located her praxis within her school. Deb followed a patterned trajectory throughout the year from questioning and evaluation of a situation to developing a plan of action. She located the need for change in other teachers at her school and questioned how she could support change in the way teachers taught mathematics and in how they worked with diverse populations of students. Deb used Nieto (2004) to reify her beliefs about the teachers in her school. By April she wondered what her role could be if others had deeply held beliefs that must be changed first, both with regard to mathematics and with regard to equity. Yet, she defined places where she could take action instead of merely identifying others as in need of change. She developed plans for the following school year which included both (a) an immersion in mathematical problem solving for teachers at school-based PDs she would be planning, and (b) approaching the principal with ideas gleaned from the Nieto (2004) text and the PD more generally as to how to address teacher expectations of the new population of students entering the school.

Discussion

We return to our initial question about the ways in which teachers' experiences in different contexts influence how they locate praxis regarding equity and the teaching and learning of mathematics. In discussing the influence of the figured worlds, we look at Deb's experiences outside of the PD and how that shaped her initial positioning. We then draw attention to Deb's experiences within her small group where our discussion centers on what Horn (2007) refers to as the "conceptual resources" teachers bring in terms of their beliefs and how individual beliefs can influence the shared belief. Finally, we explore how these influences converged in the location of of her praxis.

Influence of Membership in Particular Figured Worlds

Deb brought a particular history to her participation in the PD. These varying experiences influenced the ways in which she took up the ideas of the seminar and brought them to bear on her practice. As a result of years of living and teaching in poor sections of major cities, Deb positioned herself as an expert on equity issues within her school setting and one who was in a position to support teachers with less multicultural experience. In addition she noticed and was offended by the teachers who she perceived were dismissive of what students (particularly her target student) brought to school and who looked at the home and community environments of their students from a deficit perspective.

Influence of Context

As mentioned earlier, there are multiple contexts that influence teachers' work. In looking specifically at the PD, this study revealed the impact of group context on engagement and participation. Deb, along with other members of her group, often engaged in a self-congratulatory discourse during the discussions in the PD, not using it as a place to examine closely their own practice, but as a place to criticize other teachers at their schools. Nonetheless, Deb used her journal as a vehicle to reflect on actions that she might take. This seems to have supported her in moving toward an action plan of her own within the context of her school.

Locating Praxis

Deb's focus was on the teachers at the school level. This is understandable given that her job was that of school-based mathematics resource teacher. She was explicitly interested in supporting teachers in reaching those students who were unlike the teacher in background and/or culture. She was further interested in supporting teachers in appreciating the knowledge and strengths that children had and brought with them to school and that the teachers often dismissed. We see specific examples of this in her dismay at the ways in which the classroom teacher of her target student marginalized him within the classroom and disregarded strengths in mathematical thinking and understanding he exhibited. Deb's discouragement at making headway with this teacher caused her to abandon her efforts to support the teacher. Instead she began to work directly with the student, supporting him in developing his mathematical understandings. Yet, ultimately Deb took action at the school level, the site she identified as in need of change.

Deb turned to working with her target student when efforts to support his classroom teacher in doing so failed. Yet Deb also continued with action plans at the school level on two fronts. On one hand she considered how during the next school year she would engage teachers in school-based PD that she was planning on children's mathematical thinking. On the other hand she thought of how she could interest the principal in exploring with the faculty in the subsequent year, some of the activities in *Affirming Diversity* (Nieto, 2004).

Conclusions and Implications

This study revealed how one teacher's experiences in her figured worlds contributed to the ways she engaged with PD and where she located praxis. This is a critical finding in that PD goals may not be attained unless attention is given to teachers' experiences both in and out of PD. Specifically in this study, the initial goal of the PD was to support teachers as they identified ways in which they could change their own practice to teach mathematics with an explicit attention to equity (i.e. locating praxis within themselves; taking action in their own teaching practice). Not all of the teachers responded to the PD this way. Rather, their experiences in their figured worlds positioned them to identify other sites for praxis (i.e. locating praxis in other teachers, schools, or society). Had we been more attuned to this, as PD facilitators we could have been more responsive to where teachers were locating the need for their praxis. For example, Deb saw the need for change in others yet she took action to support them in doing so; thus her own praxis supported the praxis of others. Had our initial PD design included a space for those teachers, such as Deb, whose experiences in their figured worlds support a more active role in working with others, we could have explicitly attended to that action. In the end, we conclude that it is critical to consider the role of teachers' figured worlds on teachers' interaction with PD.

Because of the structure of this PD we had the opportunity to notice how the context of the PD was different for each group (see Wager & Foote, 2011 for a more extensive discussion of this point than this paper allows). We were able to conclude that the context of any PD is critical in supporting teachers toward action. Our initial, more limited view of the PD assumed that the structure would support teachers in thinking about praxis in their classrooms. A consideration of the teachers' experiences and the constraints or supports offered by the differing dynamics of the small groups in the PD has revealed that a broader view of PD was called for. These two topics, experiences and PD context, shaped where teachers located praxis. We suggest that this study reveals an important consideration in future PD and studies of PD.

PD to support teaching mathematics with understanding is grounded in the premise that teachers first identify the strategies that their students bring and build on that understanding. In PD on equity and mathematics, this notion is further extended to consider the funds of knowledge students bring as well. Ironically, PD on equity and mathematics does not necessarily identify the strategies and funds of knowledge that the teachers bring. As discussed earlier, scholars have identified elements of PD that have proven successful (Whitcomb, Borko, & Liston, 2009). We argue that this vision for PD should be extended so that facilitators take into consideration the experiences within figured worlds of their teachers as well as the context of the PD itself. This consideration is necessary if the goals of PD are to be met. The questions facilitators should explore include: (a) how do the structures of the PD align with teachers' experiences and (b) what opportunities do teachers' experiences offer to extend the initial goals of the PD? In examining the structure of PD relative to teachers' experiences, facilitators might first assess teachers' understandings and then determine the best organization for small group and whole group discussions. Reflecting on our PD, had we redistributed the small groups in order to take advantage of varying expertise, there may have been more even distribution of participation. In closing, we suggest that linear views of PD, in which the facilitators' goals drive the process, underestimate the learning that might actually occur.

What mathematics teachers believe about teaching ELLs affects which mathematics teaching practices they employ (Sztajn, 2003). This study compares beliefs of mathematics teachers from Illinois, Texas, and Wisconsin. Surveys and quantitative analysis methods are used to compare beliefs of teachers by district demographics (high ELL population vs. low ELL population) and region (Midwestern school districts vs. Southwestern school districts). It was found that teachers' beliefs about teaching ELLs mathematics were mostly similar regardless of comparison made. One main difference was that districts with low ELL populations looked for outside help to address challenges in teaching ELLs mathematics while high population ELL school districts relied more on their own teachers' expertise to address challenges.

Since teachers provide ELL students access to mathematics, it is essential to understand how teachers implement curricula with these students. Research studies suggest the manner in which teachers interpret and implement curricula is influenced by their knowledge and beliefs (see Thompson, 1992). Thompson (1984, 1992) reports that teachers frequently treat their beliefs as knowledge. Sztajn (2003) noted that teachers' practices were based on their conception of students' needs. A teacher may implement problem solving with students from upper socioeconomic backgrounds, while using repetitive instruction and memorization with students from lower socioeconomic backgrounds. This variation in teaching strategies and activities based on teachers' perceptions is important, because teachers may perceive that ELL students would be more successful with memorization and lecture when the opposite is true (Winsor, 2007). Creating innovative, high quality lessons for students is most likely to occur when teachers are part of a collaborative learning community supporting such experiences (McLaughlin, 1993).

In order to be equitable, it is essential that ELLs receive a high quality mathematical education (NCTM, 2000) therefore, the present study focuses on mathematics teachers' beliefs about teaching ELLs in three states, Illinois, Wisconsin, and Texas (González, 2009). The comparison of different regions allowed the researchers to compare beliefs between teachers who teach in highly and sparsely Latino-populated areas. The hypothesis of the study was that teachers in regions with large Latino populations would hold similar beliefs. It was also hypothesized that teachers in regions with small Latino populations would hold beliefs that were quite different than the regions with relatively large Latino populations.

Literature Review

Teachers' practice affects ELL students' success in the classroom (Boaler, 2002). Two factors that affect teacher practice are their attitudes towards teaching ELLs and knowledge and beliefs that motivate attitudes towards teaching ELLs (e.g. Batt, 2008; Byrnes, Kiger, & Manning, 1997).

Boaler (2002) states that teachers do not hold malicious beliefs toward teaching ELL students; they just have misconceptions about how ELL students learn. One such misconception is that teachers believe ELL students' linguistic backgrounds keep them from participating in activities requiring a higher level of cognitive demand, such as problem solving (Hansen-Thomas & Cavagnetto, 2010; Sztajn, 2003). Hansen-Thomas and Cavagnetto (2010) found that teachers from all academic fields believe mathematics is the easiest course for ELLs to study because it uses only numbers and symbols. Reeves (2006) reports that teachers believe it takes two years or less to learn English, which leads them to believe ELL students' academic difficulties are due to ability and not fluency. Cummins (1999) proposed that in fact it takes ELLs four to seven years to gain sufficient fluency that allows them to negotiate academic situations.

There are two other teacher beliefs that seem to be systemic challenges. First, teachers feel unprepared to teach ELLs (Batt, 2008; Reeves, 2006), which often makes them reticent to teach such students; however, the vast majority want to learn effective teaching techniques to use with ELLs (Hansen-Thomas & Cavagnetto, 2010). Teachers also face added responsibilities that come with teaching ELLs (Batt, 2008), such as paper work and additional meetings outside of class.

Byrnes, Kiger, and Manning (1997) and Youngs and Youngs (2001) describe several factors that affect teachers' attitudes towards teaching ELL students. Both studies found that training specific to linguistic diversity had a positive impact on attitudes towards teaching ELLs. Training such as taking a foreign language class or a multicultural class (Youngs & Youngs, 2001) are examples of training that focused on linguistic diversity. Moreover, teachers that had ELL specific training in an in-service setting had positive attitudes towards teaching ELLs.

Another factor that had a positive effect on attitudes towards teaching ELLs was more direct experiences with linguistic diversity. Experiences such as living or teaching in a foreign country are examples of direct experiences with linguistic diversity (Youngs & Youngs, 2001). Byrnes, Kiger and Manning (1997) found that the region teachers live in affected their attitudes towards teaching ELLs. Youngs and Youngs (2001) found that teachers who had students from multiple language backgrounds were more positive towards teaching ELLs. Taken together, these studies suggest that if teachers have experiences that help them better understand and relate to ELL students, then they may be more likely to have positive attitudes towards teaching ELLs.

Methods

Research Hypotheses

1) Teachers from a district sparsely populated with Latino/ELL students will have different beliefs about teaching ELLs mathematics than teachers from districts densely populated with Latino/ELL students.

2) Teachers from Midwestern districts densely populated with Latino/ELL students will have similar beliefs about teaching ELLs mathematics to teachers from a southwestern district densely populated with Latino/ELL students.

Research Participants and Settings

Eighty-six secondary mathematics teachers from school districts in Illinois, Texas and Wisconsin participated in this study. Participants were recruited from school districts meeting criteria for (high vs. low) proportion of ELLs and that had established working relationships with the researchers. The four school districts will be referred to as follows: a high-ELL urban school district in the Southwestern United States (HUs); a high-ELL urban school district in the Midwest (HUm); a high-ELL rural school district in the Midwest (HRm); and a low-ELL suburban school district in the Midwest (LSm).

School District	Study participant demographics	District population that is Latino	District population classified as ELL
HUs	76% Hispanic	92%	24%
HUm	79% Caucasian (total participants from the Midwest)	20% total population, individual schools range from 40 – 97% Latino	5 % total, individual schools range from 20% to 47% ELL
HRm		71%	52.%
LSm		5%	3%

Table 1: Description of participant and school district demographics.

Forty-two secondary mathematics teachers taught at HUs. HUs school district was chosen because it was recognized as an urban district that is succeeding in educating their students (see Kitchen, DePree, Celedón-Pattichis, & Brinkerhoff, 2006). Twenty-three participants taught at HUm and HRm school districts, which were chosen because they had similar student demographics as HUs but were located in the Midwest. Twenty-one participants came from LSm school district, chosen for comparison purposes because of the scarcity of Latino students in the district.

Instrument

Researchers generated questions for a survey that focused on teachers' beliefs about teaching ELLs mathematics. The foundation for the questions came from research conducted on teaching ELLs mathematics (see González, 2009 for details). At an authors' university, the survey was piloted with a class of preservice middle school mathematics teachers. The results from the pilot helped researchers to refine questions based on preliminary responses. Data for this study was collected using a paper-pencil or an online version of the survey, depending on the preference of the school administrators and convenience for their teachers.

The data analyzed for this report came from two different sections of the survey. One section of the survey asks, "How effective are the following strategies in helping ELLs succeed in school?" Examples of these strategies are: grouping students by language proficiency level, hiring more Bilingual Education Assistants, hiring more ESL or Bilingual Ed certified teachers, etc. Rating categories were: "Strong Positive Impact", Weak Positive Impact", "No Impact", "Weak Negative Impact", "Strong Negative Impact" or "N/A".

The other section asks teachers to share their level of agreement (on a seven-point Likert scale) on statements about teaching ELLs mathematics. Two examples of statements are, "I use the same teaching methods with English Language Learners (ELLs) as I do with Native English Speakers (NESs)" and "Technology can help ELLs learn mathematics."

Data Analysis

For each survey item, one-way ANOVAs were conducted in Minitab to evaluate the relationship between a secondary mathematics teacher's beliefs and each of the two independent variables in the research hypotheses: (1) teachers' geographic region (either Midwest or Southwest) and (2) the ELL proportion of the district's student population. The latter was categorized into two groups -- a district predominantly Caucasian (70%), and less than 3% ELLs, and districts with at least 20% ELLs. A Bonferroni correction was applied to the simultaneous tests to guard against Type I error.

Findings

The first research hypotheses that LSm School district teachers would have different beliefs than those of teachers from the HUs, HUm, and HRm school districts might be seen as true. There are several responses where LSm teachers' beliefs are significantly different than those of teachers in HUs, HUm, and HRm (see table 2). LSm teachers also gave responses that were not significantly different than the teachers in HUs, HUm, and HRm. An example of two questions where there was no significant difference are: a) ELLs can be taught to problem solve as well as Native English Speakers (NESs) can and b) ELLs have the skills and content knowledge to contribute to my class that NESs do. All teachers in the study held positive beliefs towards both of the previous statements.

The second null hypotheses that HUm and HRm school district teachers would hold similar beliefs to those of teachers from HUs school district might be seen as false. Teachers from HUm and HRm held several beliefs that were significantly different than the beliefs of teachers from HUs (See table 1). There are multiple questions from the survey where there were no significant differences between the responses of the school districts.

	Strategy teachers were asked to rate effectiveness of	Comparison	
1.	Group students by same language proficiency.		(b)
2.	Hire more Bilingual Education Assistants.	(a)	(b)
3.	Hire more ESL or Bilingual Ed certified teachers.	(a)	(b)
4.	Create an ESL consulting teachers position to help teachers in math.	(a)	(b)
5.	Use a different education model.	(a)	(b)
6.	Change the ESL curriculum.		(b)
7.	Create a sheltered English academy within the school for ELLs.		(b)
8.	ELLs can be taught to problem solve as NES can.		(b)
9.	I use a variety of teaching methods with ELLs as I do with NES.	(a)	
10.	I collaborate with my colleagues to plan lessons for my ELLs	(a)	
11.	Technology can help ELLs learn math.	(a)	
12.	I feel adequately trained to teach ELLs math	(a)	

Table 2: Statements with significant differences by comparison (a) LSm vs. HUs, HUm, & HRm (b) HUm & HRm vs. HUs.

Comparison by Districts' ELL Population

The first section's statements related to strategies in helping ELLs succeed in schools. Statements that had significant differences, with $p < 0.05$, between LSm teachers' responses and HUs, HUm, and HRm teachers' responses were 2, 3, 4, and 5. The responses were in a Likert-type scale, in which 0 meant strong negative impact; 1, weak negative impact; 2, no impact; 3, weak positive impact; and 4, strong positive impact. (see table 3)

Statement	$F(df_w,df_b)=F$	M (SD) of LSm	M (SD) of HUs, HUm, HRm	p-value
2	$F(1,69) = 18.92$	3.36 (0.63)	1.53 (1.54)	0.000
3	$F(1,69) = 33.09$	3.71 (0.47)	1.30 (1.55)	0.000
4	$F(1,68) = 21.66$	3.31 (0.63)	1.25 (1.57)	0.000
5	$F(1,58) = 5.70$	2.55 (0.69)	1.68 (1.62)	0.020

Table 3: Means, standard deviations and ANOVA results of the statements' of the two groups of districts classified by ELL population.

The second section of the survey used a scale from 1 (strongly disagree) to 7 (strongly agree), with 4 being neutral. Statements 9-12 had significant ($p < 0.05$) results (see table 4).

Statement	$F(df_w,df_b)=F$	M (SD) of LSm	M (SD) of HUs, HUm, HRm	p-value
9	F(1,77) = 9.00	5.00 (1.73)	6.00 (1.0)	0.004
10	F(1,76) = 4.90	2.64 (1.90)	3.89 (1.91)	0.030
11	F(1,79) = 5.72	5.44 (1.03)	6.08 (0.94)	0.019
12	F(1,80) = 6.25	3.00 (1.97)	4.22 (1.74)	0.014

Table 4: Means, standard deviations and ANOVA results of the statements of the two groups of districts classified by ELL population.

Comparison by Region

In the comparison between regions, all statements in the first section had significant ($p < 0.05$) results (see table 5).

Statement	$F(df_w,df_b)=F$	M (SD) of HUm, HRm	M (SD) of HUs	p-value
1	F(1,58) = 23.54	3.35 (0.99)	1.55 (1.50)	0.000
2	F(1,55) = 123.95	3.77 (0.80)	0.70 (0.88)	0.000
3	F(1,55) = 177.68	3.35 (0.86)	0.43 (0.71)	0.000
4	F(1,55) = 135.27	3.17 (1.10)	0.36 (0.71)	0.000
5	F(1,47) = 18.87	2.60 (1.06)	1.27 (0.96)	0.000
6	F(1,47) = 16.67	2.57 (1.22)	1.20 (1.00)	0.000
7	F(1,52) = 5.90	2.19 (1.38)	1.21 (1.34)	0.019

Table 5: Means, standard deviations and ANOVA results for the statements of the two groups of the two regions.

Only the statement #8, "ELLs can be taught to problem solve as NES can," had a significant difference, with $p = 0.37 < 0.05$.

Discussion

LSm vs. HUs, HUm, and HRm School Districts

The researchers hypothesized that LSm teachers would have different beliefs than the other school districts because LSm teachers and students were predominantly Caucasian. There are certain factors that promote a positive attitude towards teaching ELLs (Byrnes, Kiger, & Manning, 1997; Youngs & Youngs, 2001) and few of these are present in LSm.

For the most part, there was not a significant difference between the responses that LSm teachers provided and responses from teachers in the other three school districts. Responses to two particular questions are especially intriguing. The first question where teachers in LSm gave similar responses as teachers in the other three school districts is "ELLs can be taught to problem solve as well as NESs can." In both the literature (e.g. Hansen-Thomas & Cavagnetto, 2010; Sztajn, 2003) and in the researchers' experience working with teachers in in-service settings, mathematics teachers tend to believe that ELLs cannot engage in mathematics that require higher levels of cognitive demand. However, both LSm and the other three school districts had a positive response to the question.

The second question where LSm teachers held the same beliefs as the other three school districts was, "ELLs have the skills and content knowledge to contribute to my class that NESs do." All of the school districts had positive beliefs towards the prompt. Once again, this conflicts with the literature (Vollmer, 2000) and the researcher's experience with other mathematics teachers, school administrators, and counselors. It may be that because teachers at LSm have not had many opportunities to work with ELLs, the teachers are just hypothesizing that ELLs could contribute to their class.

One area where LSm teacher responses were significantly different than teachers' in the other school districts was mostly with the questions that addressed effective strategies that help ELLs succeed in school. The four questions where LSm teachers significantly differed from teachers in the other schools are #2-5 in table 1. In each of the four questions, LSm teachers believed that each strategy had a weak positive impact (mean $\approx$ 3) on helping ELLs succeed in school. Teachers in the other school districts believed that each strategy would have a weak negative impact (mean $\approx$ 1) on helping ELLs succeed in school. It seems that the teachers in LSm are looking for outside help with teaching ELLs. The other school districts seem to believe that they do not need outside help. Perhaps, since the HUs, HUm, and HRm teach more ELLs, their teachers believe that they are already successful and do not need external help.

There are two other questions where LSm teachers differ significantly from teachers in HUs, HUm, and HRm school districts. The first is "I collaborate with my colleagues to plan lessons for my ELLs." It is not so much that the school districts' responses to the question differ significantly that is interesting; it is that teachers' responses had means that fell in the disagree range (2.6 and 3.8 respectively, where 4 is neutral and 1 is strongly disagree). It is unsettling that all teachers in this study generally choose not to collaborate in planning lessons for ELLs. In order to ensure students, including ELLs, receive innovative, high quality instruction, the literature indicates that collaboration is essential, but is less likely when working independent of a teacher community that values such work (McLaughlin, 1993). It may be that the prevailing culture of mathematics teachers is to work independently on all lesson planning, but working to change that culture appears essential to improving the instruction of ELL students.

The other question where LSm teacher responses significantly differed from teachers' responses in the other three school districts is "I feel adequately trained to teach ELLs math." Once again, the means of the two groups raises questions. The mean for LSm is 3, meaning that they feel unprepared to teach ELLs. The mean of the other three school districts is 4.2, which is a neutral response. It seems that this finding points to the necessity of training teachers how to teach ELLs mathematics. It is not surprising that teachers from LSm do not feel prepared to teach ELLs given ELLs' scarcity. In Batt, 2008 and Reeves, 2006, it was found that teachers from districts similar to LSm did not feel prepared to teach ELLs. What is surprising is that teachers in school districts with higher proportions of ELLs did not voice feeling at least somewhat prepared as a group to teach ELLs mathematics.

HUm and HRm vs. HUs

For the majority of the questions in the survey, the HUm and HRm teachers gave responses similar to the Hus teachers. There were eight questions where HUm and HRm teachers' responses differed significantly from the responses of teachers from HUs (See table 2). Seven of the eight questions fell under the category of "strategies that help ELLs succeed in school." What is interesting is that for questions #1-4 (see table 2) HUm and HRm had means of roughly 3, which indicates that the teachers felt that the strategies would have a weak positive impact on ELL's success in school. The means for the HUs for the same questions range from 1.5 (Weak negative impact) to 0.42 (Strong negative impact). It would seem that the HUm and HRm are looking for someone to help them teach their ELLs where HUs teachers feel that they do not need outside help. Perhaps many of the teachers at HUs had tried the different strategies and found them to be less effective. For questions 5-7, all three school districts responded on the negative end of the spectrum (Weak negative impact or Strong negative impact), with the HUs teachers answering more negatively on all there questions than the other two school districts' teachers.

Implications

Follow-up interviews with teachers would help researchers more fully understand participants' responses. Despite this limitation, the findings suggest several implications. First, teachers do not feel trained to teach ELLs mathematics. There is a need for specialized sustained training aimed at mathematics teachers in order for them to learn how to effectively teach mathematics to ELLs. Next, mathematics teachers need to cultivate a culture of collaboration within their community. Regardless of the students mathematics teachers are teaching, they should collaboration dramatically increases the likelihood of planning effective mathematics lessons that engage students (McLaughlin, 1997). Finally, further research needs to be conducted to understand teachers' beliefs with respect to teaching ELLs mathematics. Once researchers more completely understand the beliefs of teachers, training can be organized to effectively address teachers' misconceptions and reinforce positive beliefs and practices.

AN EXPLORATION OF 'STUDENTING' IN HIGH SCHOOL GEOMETRY CLASSROOMS

Wendy Rose Aaron
University of Michigan
wendyaar@umich.edu

Patricio Herbst
University of Michigan
pgherbst@umich.edu

This paper examines the work that students do in instruction and the tacit knowledge that could guide this work. Classes of high school geometry students engaged with an animated scenario of geometry instruction and attempted to explain the actions of the animated students. Their responses to the animation were used to construct a model of the work of 'studenting': A set of instructional norms that partially accounted for the actions that students considered reasonable to do in high school geometry classrooms.

Objectives

As the actions that teachers take within instruction are often referred to as 'teaching,' in this study we look at the corresponding student actions, referred to as 'studenting' (Fenstermacher, 1986). We argue that studenting, while it may not be rational in the sense of correct, does reflect a rationality of sorts adapted to enacting the position of student. By the position of student we mean the expectations about how they should act in relation to the teacher, their peers, and the mathematical content they that they are expected to learn that individual adolescents come to be subject to when they enter high school. Even students who do not act according to these expectations are still exposed to them and are aware of them. It is these expectations of how a student should act that we are concerned with in this study.

This paper presents an empirical discussions of the question, 'what is the work of 'studenting' in high school geometry instruction.' The results of this study present a set of instructional norms that can be used to partially account for students' actions in classrooms. This report provides a brief example of the type of empirical analysis that was done and a brief overview of the results. For more details on this work see Aaron (2011).

The following are the primary research questions we explore in this paper:

- What are the actions that students consider reasonable to do in high school geometry instruction?
- How can hypothesized norms of instruction be used to justify student actions?

To study this question we begin with a list of hypothesized norms and examine the data to see whether and how students' comments in response to an animated classroom scenario reflect adherence to or departure from these hypothesized norms.

This paper begins with a discussion of a theoretical framework for viewing classroom interaction. We then describe the data and analytic methods used in this study. The results section consists of one in-depth example of the data supporting one instructional norm and the complete list of norms supported by the data in this study.

Theoretical Framework

To understand classroom interactions we use a model of classroom interaction developed by Herbst that is based on Bourdieu's notion of symbolic economy (1990, 1998) and Brousseau's notion of didactical contract (1997). According to this model, teachers and students act as if they are trading classroom work for claims that they have taught and learned a bit of the geometry curriculum. The foundational hypothesis is that inside educational institutions the teacher and her students enter into this economy because of their obligation to a didactical contract that brings students and teachers together to teach and learn geometry. A didactical contract specifies in rather general terms what it means to teach and learn geometry and what the geometry is that needs to be taught and learned.

The didactical contract can be modeled (by an observer) as a set of norms, or tacit rules that describe how instruction should proceed. Norms one set of cultural resources that actors use to construct their performances in particular settings. They are akin to Bourdieu's (1990) dispositions, "structured structures predisposed to function as structuring structures (p. 53)". That is, these structures for action are preexisting in the culture but when a particular actor enacts them in a particular moment they feel (to the actor and his companions) as if they are spontaneous improvisations in response to the current circumstances.

An important problem that a teacher and her students have to solve daily is to find out how the norms of the contract apply to specific chunks of work, or conversely, how their work on a specific task (Doyle, 1983; Doyle, 1988) contributes to meeting the demands of the contract. In "normal" instruction, this problem is handled through the existence of instructional situations (Herbst, 2006). Instructional situations are recurrent patterns of activity that organize the actions of the students and teacher so that they can engage in work that exchanges for claims on the contract. In general we hypothesize that these customary, recurrent patterns of activity make room for some canonical tasks saving people the need to negotiate how the contract applies for the task. In this study we focus on the instructional situations of 'making conjectures' and 'doing proofs' (Herbst & Brach, 2006). For a description of these situations see Aaron (2011).

This theoretical view of classroom interaction is useful in this current study because it highlights the role that norms play in shaping instructional activities. It also highlights the difference between instructional situations and the norms that support these situations. The results section contains three sets of norms; contractual norms that could be perceived to apply to any instructional situation in high school geometry classrooms, situational norms of 'making conjectures,' and situational norms of 'doing proofs.'

Data

The data used in this study was collected during one-time focus group sessions with classes of high school geometry students. These data come from eight classes in two schools. School 1 is a high-achieving public school serving 2,800 students in grades 9-12. School 2 is a low-achieving public school serving 1,200 students in grades 9-12. At School 1 we collected data in two honors level classes taught by Megan and two regular level class taught by Madison. At School 2 we collected data in two regular level classes taught by Jack and two remedial level classes taught by Sharleen. These schools, teachers, and classes were chosen so that the data corpus would represent a diverse group of students and experiences.

Near the end of the 2007-2008 school year the first author met with each class of students for one class period (about 50 minutes). Each class of approximately thirty students was shown the animated scenario, The Square (1), in five short clips. Each of the clips was between one and two minutes in length and highlighted the actions of a small group of animated students. The first clip was an exception because it featured only the animated teacher posing the angle bisectors problem to the class. After viewing each of the clips the moderator lead a discussion, in the form of a semistructured interview (De Groot, 2002), among participants with the aim of collecting general comments about what the participants had just viewed as well as collecting comments regarding the participants' views of the animated students they saw in the scenario.

While watching The Square, participants worked to make sense of the actions of the animated teacher and students: they reported on the actions that drew their attention, evaluated those actions, provided justifications for those actions, and suggested alternatives. These sessions were video and audio recorded and then transcribed and indexed for analysis. This indexing consisted of dividing the transcript based on the clip of the animated scenario being discussed. In the following section we describe the analytic methods that were used to examine the data and the methodology of collecting the data. We also include a description of the animated classroom scenario.

Methods

We consider the focus groups with students as modified breaching experiments (Garfinkel, 1964; see Aaron, 2011, for a full description of the use of animated scenarios as breaching experiments): The scenarios ushered students into a representation of their ordinary experiences where some of the usual features of such experience had been altered; participants were able to point to what they perceived as abnormal in familiar situations. We hypothesized that by showing participants the animated scenarios, which were designed to display actions that the participants could perceive as breaches in the normal running of a high school geometry class, we would be able to elicit from them the tacit perceptions they had of the norms of the work of being a geometry student. Because these perceptions are tacit, participants might not have been able to share them with an interviewer in a traditional interview. The immersive quality of the animated scenarios coupled with the provocation of the embedded hypothesized breaches of normal instruction prompted participants to share their perception of the geometry classroom.

Summary of the Square

The following is a brief summary of the actions of the animated teacher and animated students in The Square. This animation of high school geometry instruction was shown to the participants in this study as a data collection prompt. The animation can be seen in www.lessonsketch.org.

The Square begins with the teacher reminding her class that the angle bisectors of a triangle meet at a point. She then asks her class to make conjectures about the angle bisectors of a quadrilateral. The students work in groups on the task and then the teacher asks a student, Alpha, to share his conjecture with the class. He comes up to the board says that the diagonals of a square bisect each other. The teacher reminds Alpha that the problem is about angle bisectors, not diagonals. Alpha responds by saying that the diagonals cut the square in half and another student, Beta, interprets this to mean that the diagonals are the same as the angle bisectors. Another student, Gamma, points out that this is not true for a rectangle. Gamma comes to the board to present a counterexample. This leads to a restatement of Alpha's conjecture: The angle bisectors of a square meet at a point. The animated teacher asks the students how they might prove this and another student, Lambda, volunteers an argument using congruent triangles. After Lambda finishes, the teacher writes the 'given' and the 'prove' on the board and asks for a proof of the statement (2).

Coding for Norms

To analyze the data we look at participants' responses to the actions of the animated students. By examining these reactions one can see how appropriate the animated students' actions are from the students' perspective. The participants' comments are examined to see if they reflect a norm of instruction.

First, each comment from the participants was tagged as being in reference to a particular moment dealing with an animated student or the animated teacher. Second, within these moments, comments were summarized and similar comments were compiled. Third, the summarized and compiled comments were then coded as reflecting any situational norms. The full list of hypothesized instructional norms in not listed here but can be found in Aaron (2011).

Perceptions of animated students' actions, in relation to a norm, could be coded in one of four ways. The participants could see that the animated students complied with a norm and that this compliance was appropriate. The participants could also see that the animated students complied with a norm, however this compliance could be seen as inappropriate. That is, the participants could think that the animated student should have breached a norm. The participants could also report that a norm was breached by the animated students and that this breach was appropriate. Finally, the participants could report that a norm was breached by an animated student and that this breach was inappropriate, that is, the animated student should not have breached that norm.

Results

The follow section contains two types of results. The first is an example of the data that supports the claim that students perceived the instructional norm, *students' interventions should address the topic that the teacher has proposed*. The second is an entire list of the instructional norms, contractual and situational, that were examined in the current study.

Example of Data Supporting the Norm, Students' Interventions Should Address the Topic that the Teacher has Proposed

Below is an example of the results from this study. We describe one hypothesized norm, *students' interventions should address the topic that the teacher has proposed,* as well as animated student actions that activate this norm and evidence from the student focus groups that point to the existence of this norm. The norm *students' interventions should address the topic that the teacher has proposed* says that when students are responding to problems posed by the teacher, their responses should match that problem. This is, their responses should use the appropriate mathematical concepts, should connect their answer to the question, and students should not change the problem from how it is posed by the teacher. This norm was activated by two actions seen in The Square that are listed in Table 1. Also included is evidence from the data that supports the view that this norm was either appropriately breached or appropriately complied with by the animated students.

Table 1: Actions related to the norm, *students' interventions should address the topic that the teacher was proposing*

Action	Perceived relation to norm
A student presents an ambiguous solution	Appropriate Breach
A student provides a counterexample to another student's idea	Appropriate Compliance

The actions related to this norm are a student presenting an ambiguous solution, and a student providing a counterexample to another student's idea. These actions are preformed at different moments in The Square. In the beginning of The Square Alpha can be seen presenting an ambiguous solution, and later Gamma can be seen providing a counterexample to Alpha's idea.

A Student Presents an Ambiguous Solution (Appropriate Breach)

The participants' comments reflected the opinion that the first of these actions, a student presents an ambiguous solution on the board, was an appropriate breach of the norm *students' interventions should address the topic that the teacher was proposing*. The participants saw that Alpha's action in The Square was a breach of the norm because it was not clear how his conjecture connected to the problem that the teacher posed. However, the participants suggested reasons why it was appropriate for Alpha to provide the response that he did. Each of these reasons points to a cognitive difficultly that participants saw that Alpha could have had while working on the problem. One cognitive difficulty suggested by participants was that Alpha could have been thinking about perpendicular bisectors instead of angle bisectors. Art from Madison's third period class said that Alpha was "thinking of, like, perpendicular bisectors [instead of] angle bisectors." If this were the case, then the participants claimed that Alpha could have been making the conjecture that the diagonals of a square are perpendicular bisectors of each other.

Another cognitive difficulty suggested by participants was that Alpha did not have a fully formed conjecture, but simply had the idea to look at the case of the square. Denise from Madison's third period class said Alpha "doesn't know the answer, he just went up there and did a square." Gordon from Megan's fourth period class said, "Sometimes it's hard to put your thoughts into words especially if you are, um, shaky on the topic, so I think that's kinda what happened to Alpha." Gordon explains Alpha's breach of the norm by hypothesizing that the material was taxing for Alpha and therefore it was difficult for him to communicate his idea.

These comments from participants support the norm that *students' responses should address the problem* and provide an example of a cognitive difficulty that participants attribute to Alpha to explain why he was unable to comply with the norm. The participants see Alpha attempting to answer the animated teacher's questions but lacking the mathematical understanding needed to provide an acceptable conjecture.

A Student Provides a Counterexample to Another Student's Idea (Appropriate Compliance)

The participants' comments reflected the opinion that the second of these actions, a student provides a counterexample to another student's idea, is an appropriate compliance with the norm *students' interventions should address the topic that the teacher has proposed*. Participants saw that Gamma's contribution of thinking about the diagonals and angle bisectors of a rectangle was a counterexample to Alpha's conjecture and had an important mathematical component in terms of answering the problem posed by the teacher. That is, Gamma noticed that Alpha's conjecture was only true for squares and that Alpha's conflation of angle bisectors and diagonals is only non-problematic in certain quadrilaterals. The participants recognized Gamma's point, that in rectangles the angle bisectors are not the diagonals, as a mathematically valid point to make because the problem posed by the teacher is about quadrilaterals in general, not only squares. Bob from Madison's third period class said, "[Gamma] was trying to make it more general because [Alpha] was just talking about a square." Bob's comment reflects the opinion that it is appropriate for Gamma to provide a more general response than Alpha, which was too specific to answer the question posed by the teacher.

Also in light of Gamma's counterexample and this norm, some participants said that special cases, like Alpha's square, are not useful or are irrelevant when responding to general questions, like the angle bisectors problem. Muna from Megan's third period class said, "[Gamma] was just trying to point out that, um, what Alpha was saying was sort of irrelevant because they were talking about all quadrilaterals not just squares. So, I guess, answer the actual question." This comment from Muna highlighted the view that Alpha's conjecture did not address the teacher's problem, so it was appropriate for Gamma to provide a counterexample that was more clearly connected to the teacher's problem.

Other participants agreed that Gamma was making a distinction between squares and other quadrilaterals, but unlike Muna, these participants did not see the hierarchical relationship between squares, rectangles, and quadrilaterals so they did not see that Gamma's counterexample was a move towards answering the teacher's problem. Mary from Madison's third period class said, "Like, I don't know if [Gamma] realized it, but she was kind of saying that the rules for the squares are different than the rules for the rest of the quadrilaterals." Mary's comments showed recognition of Gamma's counterexample, but did not award mathematical value to Gamma's move from squares to rectangles.

The norm *students' interventions should address the topic that the teacher has proposed* was activated twice. The participants saw that it was appropriately complied with once and appropriately breached once. In the first case the participants saw that the norm was appropriately breached because a student did not have the cognitive capabilities to respond to the problem that the teacher posed. On the second case the participants saw that this norm was appropriately complied with since a student provided a counterexample to another student's idea. The participants saw that Alpha provided an answer to the teachers' question that only addressed a special case, so Gamma appropriately expanded on Alpha's response to make it a better answer to the teacher's original question.

List of Contractual and Situational Norms

The following is a list of the norms that were elicited in the conversations with the focus groups of high school geometry students. The first column labels the specificity of the norm as either applying to all instruction through the didactical contract, or only in the situations of 'making conjectures' or 'doing proofs.' The second column lists the norm. The third column describes the student action from the animation that prompted participants to discuss the norm. The final column relates the participants' stance toward the perceived norm.

	Norm	Action	Perceived relation to norm
Contract	*Students should share their ideas that are different than other students' ideas*	A student comes to the board to share her idea	Appropriate Compliance
	Students should complete incomplete arguments given in class	A student whispers a contribution to a solution	Appropriate Compliance; Inappropriate Breach
	Students' interventions should address the topic that the teacher has proposed	A student presents an ambiguous solution	Appropriate Breach
		A student provides a counterexample to another student's idea	Appropriate Compliance
	Students should be disposed to share ideas in public when so asked	A student is hesitant to present his solution at the board	Inappropriate Compliance
		A students shares his solution from his seat	Inappropriate Breach
	Students in the audience should support the presenter in public	A students whispers while another student is presenting a solution at the board	Appropriate Compliance
		A student clarifies another student's idea	Appropriate Compliance; Inappropriate Breach
	Students should be amenable to assessment	A student shares an ambiguous idea with the class	Appropriate Compliance
'Making Conjectures'	*Students should communicate their conjectures to the class*	A student is hesitant to share his idea at the board	Inappropriate Compliance
		A student whispers while another student presents a solution at the board	Appropriate Breach
		A student clarifies another student's conjecture	Appropriate Compliance
	Students can respond to other students' conjectures	A student provides a counterexample to another student's idea	Inappropriate Compliance
	Students should stop talking about a conjecture once it has been agreed upon or refuted	A student comments on a conjecture after it has been agreed up on or refuted	Inappropriate Breach

'Doing Proofs'	*Students should not make changes to the proof problem*	A student requests to modify a problem	Appropriate Breach

From these results one sees that the participants, while responding to the animated scenario, did provide evidence to support the hypothesized norms. This list of hypothesized norms is not a complete list, at least in regard to the norm 'doing proofs' in geometry instruction (Herbst & Brach, 2006; Herbst et al., 2009), but it does reflect the primary norms that can be seen to be active in The Square. Unlike previous research on instructional norms in geometry classrooms, this study focuses both on perceptions of norms during instruction (unlike Herbst & Brach, 2006 which focused on students' perceptions of norms while working on proof tasks in isolation) and on instructional norms from the students' point of view (unlike Herbst et al. 2009, which primarily looks at instructional norms from the perspective of the teacher).

Discussion

By understanding the student's position in geometry instruction we will be better able to understand geometry instruction as a whole. Understanding the complex system of geometry instruction is the first step to making informed improvements to the system. A change in curriculum could result in an unexpected student action that could be explained in terms of an instructional norm. That is, changes to any part of the system should take into account their effect on other parts of the system, and these possible interactions can only by predicted by first understanding the system as a whole. The current paper represents an attempt in that direction.

Unlike teachers, students go through no professional training for how to be a student, so their actions are guided solely by the rationality that they develop from doing the work of studenting. There is, therefore, a self-perpetuating relationship between studenting and the rationality of studenting. The actions that students engage in mold the rationality of studenting and the rationality of studenting shapes future actions. It is difficult, if not impossible, to change students' instructional actions directly, but if we can uncover the rationality of studenting we can use this as a lever for changing student action (see Lampert, 2001, chapter 10). The first step after understanding student rationality would be to design instructional activities where students' rationality could be use to enable instruction. That is, in cases where students' actions are undesirable due to students' interpretation of a task or situation, that task or situation could be reengineered in such a way that the students' rationality would result in more beneficial instructional actions. As students spend time engaged in mathematical tasks, performing actions that embody more desirable mathematical work, then their rationality of studenting could possibility change to naturally support more productive mathematical work.

Endnotes

1. The Square, along with all of ThEMaT's animated scenarios, can be viewed at www.lessonsketch.org

2. The authors would like to acknowledge the work of Ander Erickson in developing this summary of The Square.

This article focuses on six fifth grade students' responses to area measurement tasks involving square and right triangular units. Data were collected during individual interviews as part of a four-year teaching experiment. Although all six students were able resolve a square unit area measurement task, they struggled to resolve similar tasks with right triangular units. Results indicate that engaging in the triangular unit tasks helped our students realize the necessity of coordinating linear measurements, relating linear and area units, and constructing and iterating a row (or column) composed of identical units. Implications for instruction and future research are discussed.

The importance of area measurement is evident in both daily life and school mathematics. As students study area measurement, they "develop ways to mentally structure the spaces and objects around them," which provide a context for the development of mathematical reasoning (Cross, Woods, & Schweingruber, 2009, p. 35). However, most elementary and middle school students have developed an inadequate understanding of area measurement concepts (Outhred & Mitchelmore, 2000). In 1986, only 40% of 13-year old students correctly answered that the area of a 6 cm by 4 cm rectangle (with only these number labels demarcating the dimensions of length and width) was 24 square centimeters on the Fourth National Assessment of Educational Progress [NAEP] (Lindquist & Kouba, 1989). More recently, in 2000, only 14% of 13-year old students could determine the number of square tiles to cover a rectilinear region with number labels demarcating the dimensions on the Eighth NAEP (Sowder et al., 2004).

Kordaki and Potari (2002) and Outhred and Mitchelmore (2000) attributed the lack of understanding area measurement to the required coordination of multiple ideas. "The concept of area measurement is a rather complicated one for students to grasp as it consists of a network of concomitant related concepts: the conservation of area, the unit and its iteration and the counting of units" (Kordaki & Potari, 2002, p. 65). Other researchers have formally asserted that this inadequate understanding of area measurement is characterized by a rote application of the rectangular area formula (Simon & Blume, 1994). A relational understanding of the area formula depends on students' abilities to develop an understanding of *multiplication-as-repeated addition with the notion of an iterated row of identical area units* (Outhred & Mitchelmore, 2000; Sarama & Clements, 2009). Thus, research has demonstrated that students can structure a two-dimensional array and use the rectangular area formula by rote but without understanding crucial area concepts and principles, including identification of unit, coordination of linear and area units, tessellation of the plane, and relation of area measurement to multiplication (Battista, 2003; Clements & Sarama, 2007).

When area measurement is focused on counting units, students are sometimes unable to link area measurement to a structure that is two-dimensional and multiplicative (Outhred &

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

Mitchelmore, 2000; Sarama & Clements, 2009). Research indicates that the use of physical tiles and square units has the potential to hide misunderstandings. Using concrete materials to tile a rectangular figure "may conceal the very relations they are intended to illustrate" (Outhred & Mitchelmore, 2000, p. 146). Because manipulatives pre-structure the array, students can correctly determine the area of a region without attending to the structure (Lehrer, 2003; Outhred & Mitchelmore, 2000). Thus, removing the concrete manipulatives has the possibility to reveal misconceptions.

Using square units to cover a rectangular figure – even if the concrete materials are not available – allows students to determine correctly area without attending to both dimensions. Because the rectangular array structure is not self-evident for children (Battista, Clements, Arnoff, Battista, & Borrow, 1998), they often imitate global organization without conceptually understanding it. In other words, some students can correctly structure an array with square units by relying on discrete counting of objects and using one-dimensional structuring techniques, or partial row structuring (Battista et al., 1998; Sarama & Clements, 2009). Students using one-dimensional structuring techniques struggle to *coordinate the linear measurements* because they do not use the width and the height of both the unit and the region. This coordination is especially non-trivial with non-square units when the orientation of the unit with respect to the region matters. These students also struggle to *relate linear and area units* because they do not understand the concept that the side length determines the number of area units that will fit along that length (Battista, 2003; Outhred & Mitchelmore, 2000; Sarama & Clements, 2009). However, missing from the literature is how students structure rectangular regions when provided with non-rectangular, non-concrete area units.

Theoretical Framework

The tasks presented here have been designed as part of our efforts to test and improve a hypothetical learning trajectory for area measurement (Sarama & Clements, 2009). A hypothetical learning trajectory consists of three components: a learning goal, a likely path for learning as students progress through levels of thinking, and the instruction that guides students along the path (Sarama & Clements, 2009). We used the hypothetical learning trajectory to focus our attention on students' internal representations, or mental images, and their external representations, or drawings, in the context of area tasks. In the construction of the hypothetical learning trajectory for area, Sarama and Clements (2009) reflected upon the interactions between external and internal representations, giving equal credit to how students construct both of them. This trajectory also guided our ideas concerning the underlying conceptual foundations of area measurement in terms of comparing, connecting the iteration of identical rows of area units with an understanding of multiplication-as-repeated addition, relating linear and area units, and coordinating linear measurements.

Purpose

It is our conjecture that area tasks involving only square units are not sufficient for revealing students' conceptions or misconceptions regarding area measurement. We claim that tasks involving right triangular units provide a rich context for teachers and researchers to investigate and also develop students' understandings of area structuring. We believe these tasks provide an opportunity for students to demonstrate their ability to adapt the standard area formula, which in these instances will not result in the number of triangular units needed to fill a region. The purpose of this report is to describe and analyze student responses as they engaged in area tasks involving right triangular units, specifically in terms of relating linear and area units, coordinating linear measurements, and understanding multiplication-as-repeated addition.

Research Question

1. How do area measurement tasks involving triangular units impact students' ability to relate linear and area units and coordinate linear measurements?
2. How do area measurement tasks involving triangular units impact students' application of the area formula?

Methodology

The sample consisted of six children (Abby, Anselm, Arielle, Danny, Jessie, and Owen) from two fifth grade classes at a Midwestern public school. Each student has been regarded as a case study within a four-year longitudinal study investigating children's thinking and learning across length, area, and volume for Grades 2-5.

The tasks described below were developed within the context of a teaching experiment (Steffe & Thompson, 2000). The teaching experiment consisted of a series of teaching episodes for which the research team generated a set of tasks and predictions for student responses and then later checked student responses against these predictions. Each teaching episode was videotaped, transcribed, and analyzed by a group of researchers, the authors. In this report, we consider data collected in a single teaching episode consisting of two 25 to 30 minute interviews, an initial interview and a follow up interview, for each student during the months of October and November of 2010.

We varied the tasks in terms of the area unit provided and followed the sequence of a square and two right, scalene triangular units. These task variations allowed us to assess and compare students' performance with the traditional square units as well as triangular units.

The development of each task we posed in this teaching episode was guided by a two-step framework (Cullen et al., 2010). We presented the students with two figural objects, a unit and a rectangular region, and asked them to compare the objects by area. We then asked, "How does the area of this tile compare to the area of the larger region?" If the student gave a qualitative comparison, we asked, "How much bigger?" in order to elicit a quantitative comparison. We conjectured that these two steps would draw students' attention to the underlying concepts of area measurement: comparing, connecting the iteration of identical rows of area units with an understanding of multiplication-as-repeated addition, relating linear and area units and coordinating linear measures.

Initially, we did not allow the students to use a writing utensil or their hands in order to prompt them to verbalize their internal representations of the area structuring. As a second part of each task, we asked the students to show how the unit would cover the region by drawing or creating an external representation. This allowed us to attend to both students' internal representations, or mental images, and their external representations, or drawings to be consistent with the learning trajectory in our analysis of students' understanding of area measurement.

The interviewer inferred the strategies children used to solve area tasks through both careful questioning as the students provided verbal descriptions of their internal representations and observations as students created external representations. The data analysis involved identifying and then classifying students' strategies for solving each of the four area tasks. Next, these classifications were examined for commonalities and variations among the six students.

Results

The results for this study are presented below and include descriptions of student responses to each of the three tasks. In each task, we asked students to compare an area unit of measure and a rectangular region to be measured, first verbally and then using their hands and a writing utensil to record their thinking.

Task 1: Compare area of a 5 by 7 rectangle to area of a 1 by 1 square-unit inside rectangle

The area unit for Task 1 was a square, inside of a rectangle (Figure 1). The linear units were represented as number labels on rulers along each side of the rectangular region.

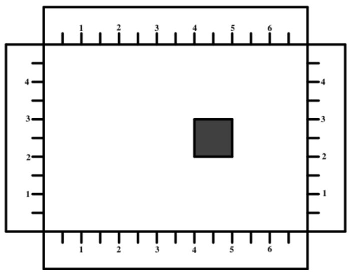

Figure 1. Task 1

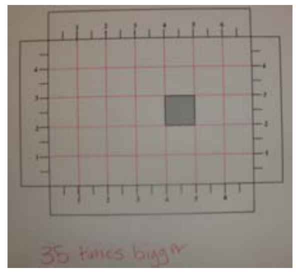

Figure 2. Abby's drawing for Task 1

Five students, Abby, Arielle, Danny, Jessie, and Owen, correctly used the rulers to determine the dimensions and correctly applied the rectangular area formula (i.e., $a=lw$) to calculate mentally that 35 squares would cover the rectangle without drawing. The sixth student, Anselm, used the rulers incorrectly, reporting the last numerals displayed on the rulers as the dimensions, thus missing the final linear unit for each. When asked to make a record of his thinking, Anselm drew one row of the units, realized that there were 7 units instead of 6, and changed his answer to 35. All six students could show how the tiles would cover the rectangle by either drawing the individual tiles or alternating between drawing individual units and parallel row and column line segments. Abby's drawing was the most sophisticated; she was the only student to draw a complete covering of parallel line segments from the linear unit markings on the four rulers to form a row and column structure of square area units (Figure 2).

Despite the variety in their drawings, all six students aligned square-units in rows and columns. All of them seemed to relate length and area units, coordinate linear measurements, and apply the rectangular area formula with understanding.

Task 2: Compare area of a 9cm by 8cm rectangle to area of a 3cm-4cm-5cm right triangle

The area unit for Task 2 was a right, scalene triangle (Figure 3). The linear units were represented as number labels along each segment in both the rectangle and the unit.

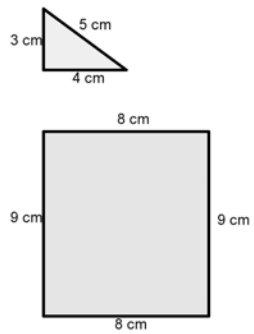

Figure 3. Task 2

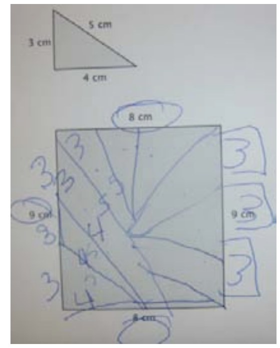

Figure 4. Owen's drawing for Task 2

Owen was the only student who could give a correct answer before drawing. All of the students except Jessie eventually resolved the task correctly by drawing. Owen discussed constructing columns of rectangles composed of triangles. Despite his correct explanation, he drew an entirely different representation without conserving the shape of the triangular area unit (Figure 4). After Owen completed his drawing, the interviewer asked him to reflect on his work in the preceding task in which he constructed a correct drawing of rows and columns of units, which is not mentioned here. This seemed to prompt him to draw row and column line segments; thus, he drew a second covering of triangles in rows and columns consistent with his initial verbal description. Jessie and Abby drew a complete covering of two columns and two rows of rectangles composed of triangles but did not attend to both dimensions. With prompting to think about what the number labels were referring to, Abby coordinated linear measurements and drew a correct covering.

Anselm and Danny gave incorrect initial estimates; however, while drawing, they correctly attended to linear measurements and operated on columns of rectangles composed of triangles. Arielle operated arithmetically on measures and thought about covering with columns of rectangles composed of triangles. She applied the area formula to both the rectangular region and the rectangular composite unit; she divided these quantities and obtained a quotient of 6. However, she incorrectly reasoned that she needed 5 more rectangular units or 10 more triangular units to cover the rectangle. When asked to make a record of her thinking, Arielle used both dimensions to correctly draw three rows and two columns of completed triangles inscribed in rectangles and stated that 11 more triangles would be needed.

Although all of the students successfully resolved Task 1, Task 2 was a challenge for them. During this task, we noticed that students struggled to resolve the task without drawing, to relate linear and area units, to connect linear measurements, and to connect the iteration of identical rows of area units with an understanding of multiplication as repeated addition.

Task 3: Compare area of a 12 by 8 rectangle to area of a scalene right triangle

The area unit for Task 3 was a right, scalene triangle (Figure 5). The linear units were represented as tick marks around the inside border of the rectangular region.

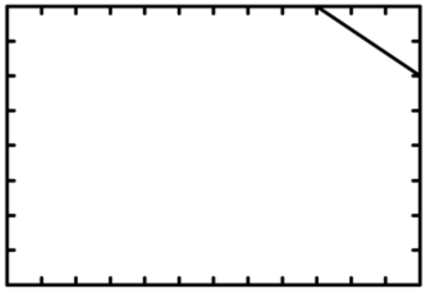

Figure 5. Task 3

Figure 6. Jessie's drawing for Task 3

Each student discussed the placement of units in rows or columns, but only three students, Arielle, Abby, and Owen, successfully resolved the task without drawing. Danny and Anselm used a non-adaptive area formula to resolve the task before drawing. Danny discussed placing eight triangles in a row and eight triangles in a column. He multiplied these quantities and said that the area of the rectangle would be 64 triangular units. Anselm discussed placing four columns and four rows but then multiplied 12 by 6 for an area of 72 triangular units, which he was unable to explain. While drawing, both Danny and Anselm realized their initial errors. Arielle, Abby, Owen, Danny, and Anselm attended to an organized row and column structure and related linear and area units in their drawings. The only student who did not resolve this task successfully was Jessie. She described a row and column structure of three rows of eight triangles for a covering of 24 triangular units. As she drew these three rows of eight units aligned in columns, she attended to only one dimension (Figure 6).

Discussion

Throughout the analysis of the students' responses and strategies when working with triangular units in area measurement, three main themes emerged. The first two themes concerning the underlying conceptual foundations of area measurement are already present in the existing area hypothetical learning trajectory (Sarama & Clements, 2009): 1) relating linear and area units and coordinating linear measurements and 2) connecting the iteration of identical rows of area units with an understanding of multiplication-as-repeated addition. The third theme emerged as the learning trajectory focused our attention toward students' internal and external representations; some mismatches appeared. The themes are explained in detail below.

1. Relating linear and area units and coordinating linear measurements

In Task 1, all six students correctly computed the area in terms of square units and justified their answers by showing how the tiles would cover the rectangle. In this task, Abby covered the array solely with row and column line segments. However, when covering with triangular units in Task 2, she demonstrated less sophisticated drawing strategies and only attended to one dimension. After Abby was prompted to use the linear measurements for both dimensions in Task 2, she not only resolved the task correctly, but also successfully drew an array in Task 3 with single row and column line segments. In other words, Abby's covering of a region with triangular units improved after she realized the necessity of coordinating linear measurements and relating linear and area units. Although Jessie successfully resolved Task 1, she was unable to coordinate linear measurements and relate linear and area units for the triangular unit tasks. While all six students seemed to demonstrate an understanding of the conceptual foundations of area measurement when working with square units, they were unable to do so when working with triangular units.

2. Connecting the iteration of identical rows of area units with an understanding of multiplication-as-repeated addition

By analyzing the results of Task 1 in isolation from the rest of the tasks, one could assume that the students were applying the area formula for rectangles meaningfully for square units. However, conflicting results occurred with the use of triangular units in the subsequent tasks. Therefore, we can conclude that they are unable to adapt the area formula, missing the underlying process. For example, Arielle's unit confusion in Task 2 made her end up with incorrect calculations as a result of inappropriate use of the formula. For Task 3, both Anselm and Danny applied a non-adaptive area formula; they did not connect using multiplication for area measurement with counting the number of area units needed to cover. In other words, their multiplication did not reflect the construction of a column as a composite unit of triangular units or the application of this composite unit repeatedly over the rectangle to cover (Sarama & Clements, 2009). The students did not have an understanding of why multiplication generates an array for square-units (e.g. Lehrer, Jaslow, & Curtis, 2003; Lehrer, 2003); as a result, they incorrectly applied the same formula for the triangular units.

3. Connecting internal and external representation

Asking students first to compare areas of regions without using their hands or a writing utensil and then to create a drawing of their thinking revealed some mismatches between students' internal and external representations. For example, Anselm gave incorrect initial answers for Task 1 when explaining his thinking. For this task, he counted incorrectly and realized his error while drawing, or translating his internal representation to an external representation. The drawing intervention also seemed to help Arielle and Abby. In contrast, Owen initially gave a clear description of his internal representation, which was correct. However, his external representation in the form of a drawing did not match his well-structured, internal representation as he described. These results indicate that some students, such as Anselm, Arielle, and Abby, may need to show their internal representations as external representations in order to correctly resolve tasks. However, for other students, such as Owen, showing their internal representations as external representations may be a challenge. The results of this study indicate that students' external representations may be mismatched from their internal representations.

Conclusion

Although all of the students successfully resolved the square unit task (Task 1), the results from the triangular unit tasks (Tasks 2 and 3) indicate that students may have a disconnect between the area formula and underlying area measurement concepts, including relating linear and area units, coordinating linear measurements (Battista, 2003; Outhred & Mitchelmore, 2000; Sarama & Clements, 2009), and connecting multiplication-as-repeated addition with the notion of an iterated row of identical area units (Outhred & Mitchelmore, 2000). By working with right triangular units, our students were confronted with novel situations, causing them to reflect upon their rote area measurement conceptions. We found that these tasks challenged them to adapt and extend the rectangular area formula to cope with this new situation. Engaging in these tasks helped our students realize the necessity of coordinating linear measurements, relating linear and area units, and constructing and iterating a row (or column) composed of triangles. These results indicate that students need more meaningful experiences with building and iterating identical rows (or columns) of area units to understand why multiplication works for determining the area of rectangular arrays using square units. We suggest that one such experience is to compare covering rectangular regions with square units to covering with triangular units.

By focusing separately on students' internal representations, or verbal descriptions of their mental images, and their external representations, or drawings (Sarama & Clements, 2009), we revealed mismatches between these representations. Therefore, in order to probe students' understanding in area measurement comprehensively, we suggest that researchers and classroom teachers ask students to describe their internal representations verbally and to display what they are thinking by creating external representations. One cannot assume that students' external representations are congruent to their internal representations.

Because of our small sample size, our conclusions concerning right triangular unit tasks can be regarded as researchable conjectures regarding fifth grade students' conceptions of area measurement. Further research is needed to investigate these conjectures across grade levels and in the context of classroom studies to establish the effectiveness of developing students' understanding of area measurement with non-square units, including but not limited to triangular units.

Dr. Karen Allen Keene
North Carolina State University
karen_keene@ncsu.edu

This study expanded on research about incorporating technology into the geometry classroom by investigating specifically how the technology is used and if the different methods have any effect on students' conceptual understanding of angle. The primary purpose was to discover whether it would be beneficial for students to create their own constructions with Dynamic Geometry Software given definitions or discover definitions using teacher-constructed diagrams while learning the concept of angle. We provide evidence that students' understanding improved more when they were given teacher-constructed diagrams to learn the concept. Additionally, certain subgroups of students benefited from the DGS in more significant ways.

Introduction

Envision a class of average geometry students who had learned bits and pieces of geometry throughout several mathematics courses and enter into their only high school geometry class with previous knowledge from a variety of somewhat disconnected instructional experiences. As they discussed the description and properties of angle after looking at a geometric figure in a Dynamic Geometry System (DGS), one student defined angle as "basically a bend in a line, so it becomes two rays coming out of a single point." While two students analyzed a dynamic diagram of an angle they discussed how the degree of the angle "either increases or decreases and goes in a 360 degree" rotation. Finally when a student is asked to identify the angles in a quadrilateral you listened to a student express how a quadrilateral contains only four angles, "unless you count the over 180-degree ones," which would bring the total to eight angles. The question of how to best use DGS in a classroom is motivated by these kinds of experiences with students in classrooms.

Additionally, in recent years, more classroom emphasis has been placed on the multiple definitions of angle; research shows that the concept of angle is hard to comprehend (Keiser, 2004, p. 286). This can be a significant learning issue for students without which they cannot completely understand geometry or how an angle is represented every day in their lives. Therefore, we paid close attention to high school geometry students' understanding of angle and how to understand this essential concept with the use of technology. By connecting these two research areas, student understanding of angle, and DGS as a tool for instruction, we expanded upon the research on incorporating technology into the geometry classroom by concentrating on how the technology is incorporated and if the method has any affect on students' conceptual understanding. The primary purpose was to research whether it would be beneficial for students to create their own constructions with DGS or discover new information using teacher-constructed diagrams while learning the concept of angle. This new research will contribute to the mathematics education literature as well as provide ideas for using DGS in the classroom.

Literature Review

Angle

Close (1982) studied the assortment of angle definitions used in mathematics along with many authors who have noted the difference between the definitions as well as between dynamic (movement) and static (configurational) angles (Close, 1982; Kieran, 1986). In the traditional high school geometry class curriculum the definition of angle used is the definition described by Euclid. According to *The Elements* an angle is “the inclination to one another of two lines in a plane which meet one another and do not lie in a straight line” (Health, 1956, p. 153). Euclid then continued to define angle introducing what we refer to in this research as the straight angle in which “the lines containing the angle are straight” this angle is called rectilinear (p. 153). “When Euclid specified the rectilinear angles contain straight lines, he was suggesting that other angles could be composed of lines that are not straight” instead they are curved (Keiser, 2004, p. 297). Mitchelmore and White (1998) suggested three different definitions in which the conceptual understanding of angle can occur. They proposed that an angle could be a rotation, a pair of half lines that extend from a common point, or as angle in a curve. These definitions were used in our study.

There are several articles that provide evidence that students have difficulty understanding the concept of angle (e.g. Mitchelmore & White, 1998; Munier & Merle, 2009; Kieran, 1986; Close, 1982; Clements & Burns, 2000). In elementary school, when students are introduced to the concept of angle, they are given a pictorial representation of an angle and taught how to classify it by measurements without really understanding the concept but instead memorizing a picture and a definition (Keiser, 2004). Keiser continues to explain that teachers consider the concept of angle to be a difficult concept to teach even at a preliminary level of understanding. Students do not understand the concept that the size of an angle has no dependency on the length of its rays (Munier & Merle, 2009, p. 1865). Close (1982) discussed the difficulty that students have the understanding that two rays with the same endpoint actually compose two angles. According to Close (1982) students have a hard time understanding that these two angles add up to 360˚.

Clements and Battista (1989) and Kieran (1986) discuss the fact that students often have many misconceptions about angle and experience difficulty learning the complex topic. In order to better prepare students for future mathematics courses teachers should use a more comprehensive approach, presenting angle using the variety of definitions given throughout history (Keiser, 2004). Teaching a diverse array of definitions may cause confusion about what is actually being measured when referring to an angle and therefore angle should be taught in great depth with concern for conceptual understanding as to reduce any misconceptions the students may gain with this multifaceted approach (Keiser, 2004).

Clements and Burns (2000) also mention a different misconception held by students about the turn of an angle and how they find it difficult to measure turn. In order to master this concept Clements and Burns (2000) use a piece of DGS called LOGO. “LOGO activities can be beneficial to students’ development of turn concepts and turn measurement” (Clements and Burns, 2000, p. 31). LOGO provides a situation of visualizing the turn of an angle (Clements and Burns, 2000). With the use of LOGO, students build active and flexible conceptual protractors unlike the traditional protractors used in everyday classrooms (Clements and Burns, 2000). The research on LOGO provides knowledge that supports the DGS research in angle.

Dynamic Geometry Software

Monoghan’s research supports the use of software can help the students' understanding of the concept “more easily than otherwise possible. Geometry software can provide dynamic diagrams that students can manipulate to understand concepts, which can't be done with traditional paper diagrams (Hollebrands, Laborde & StraBer, 2008). "When an element of such a diagram is dragged with the mouse, the diagram is modified while all the geometric relations used in its construction are preserved. … It is as if diagrams react to the manipulations of the user by following the laws of geometry, just like material objects react by following the laws of physics" (Hollebrands, Laborde & StraBer, 2008, p. 167).

A study conducted by Erez & Yerushalmy (2006) concluded that it is beneficial and "important to the study of learning basic concepts in geometry with the aid of the dragging tool" seen in a variety of DGS (p. 293). "Dragging allows changing a shape by direct translation of parts of its components on the screen… dragging the shape preserves the geometric relations according to which is was initially defined. Thus the critical attributes associated to this definition are preserved during dragging but the non-critical attributes are changed" (Erez & Yerushalmy, 2006, p. 274). Unlike constructing diagrams with pencil and paper, DGS can help students not only construct the diagrams but by being able to drag the points, lines, segments they can discover new information using previous knowledge (Skemp, 1976). Using previous knowledge with well-connected, conceptually grounded ideas provide a greater opportunity for students to gain a deeper understanding of the concept (Skemp, 1976).

Students may learn properties of the geometric representations with DGS, since the properties hold according to the constructions, and there could be fewer misconceptions due to the manipulation of the diagrams. There are numerous studies that have been conducted about the use of DGS in geometry classrooms. Mitchelmore and White (2000b) advocate a teaching method called 'teaching by abstraction', wherein 'students become familiar with several examples of the concept before teaching the concept itself." This kind of teaching works well with dynamic diagrams if it involves some exploration of the concept (familiarity). Then 'the concept is taught by finding and making explicit the similarities underlying familiar examples of that concept' (similarity). Lastly, 'as students explore the concept in more detail, it becomes increasingly mental object in its own right' (Munier & Merle, 2009, p. 1861).

Another study by Monaghan (2000) brought about similar results as the study by Erez & Yerushalmy (2006). "In this study, the cognitive conflict is brought about by asking students to describe in their own words the differences between pairs of quadrilaterals" (Monaghan, 2000, p. 180). Monaghan's (2000) underlying assumption is that students will gain a deeper understanding through conversation and hopefully reveal insights about quadrilaterals with the use of software and class activities creating an environment in which students can learn and share their discoveries (p. 180). The study concluded that these misconceptions about quadrilaterals would be reduced using software to aid the instructional activity, allowing students to explore their ideas about quadrilaterals.

The importance of technology in the mathematics classroom has been investigated through a variety of venues about a variety of topics throughout mathematics education research. This study is designed to use this research and expand upon it while investigating the importance of angle comprehension in the geometry classroom.

Methodology

The following research questions frame the overarching idea of researching whether using teacher-constructed sketches, called pre-constructed sketches by Sinclair (Sinclair, 2003, p. 289) or student-constructed sketches were more effective when teaching the concept of angle.

1. How do students learn the concept of angle supported by the use of dynamic geometry software and does the use of dynamic geometry software support diverse subgroups of students differently?
2. How is student learning of angle influenced by the use of student-constructed diagrams compared to the use of teacher-constructed diagrams using dynamic geometry software?

The study took place in the spring of 2010 in two academic geometry (non-honors) high school classrooms at the same urban school located in a large city in the Southeastern United States. There were a total of 27 subjects. In the SCD class, there were 7 females and 8 males, with more than half of the subjects being black or Hispanic. In the TCD class, there were 8 females and 4 males with the majority of the subjects being black. The student's ages ranged from 15 years of age to 17 years of age. Each of the subjects was first introduced to DGS in the current geometry classroom. The teacher and primary researcher had three years of previous teaching experience in two different schools. She has a bachelor's degree in mathematics education, has since completed her Master's Degree in Mathematics Education, and is pursuing a PhD in Mathematics Education.

The study consisted of a pre-test for students (45 minutes on Day 1), instruction using DGS in two different formats described below(270 minutes on Day 2, 3, and 4) and a post-test for all students (45 minutes on Day 5 which was 4 weeks after the completion of the instructional activity). The two classes were randomly assigned to be the student-constructed diagram (SCD) class and the teacher-constructed diagram (TCD) class. Each class was given the same pre-test and post-test but the two classes participated in a different set of instructional activities. The students in the SCD class were given definitions of introductory terms in geometry and asked to construct pictorial representations based on the definitions. The students in the TCD class were given teacher-constructed diagrams, figures created in DGS by the teacher prior to class, of the same terms as in the SCD instructional activity and asked to provide the definitions to go along with the pictorial representations. In both classes, the students worked as pairs in order to gain a deeper understanding through discussion and were required to expand upon prior knowledge from previous mathematics courses. Allowing this type of collaborative work helped the students gain a wide range of understandings (Keiser, 2004).

In both classes the students worked individually on their computer but discussed their findings with the DGS as a pair while they recorded their results on their investigation. After the students in both classes completed the three days of instruction using the DGS class continued as normal, going through the curriculum until a month had passed. One month after instruction, the students were given the post-test. There were also nine questions in the post-test similar to the questions in the pre-test, the questions were superficially different yet conceptually the same. The only question that differed conceptually was question 8; therefore, it was not used in the analysis of the study. The pre-test and post-test were used to compare the results in order to discover if the students showed a deeper understanding of angle due to the instructional activity, if any subgroups of students gained a better understanding with the instructional activity, and if one activity was more efficient than the other.

Data Analysis

Data analysis consisted of both qualitative and quantitative analysis. After the collection of data in the pre-test, instructional activity, and post-test all of the written responses were entered into a spreadsheet in order to make conjectures from patterns throughout the subjects and the questions. The written responses were coded and assigned a number to represent their level of understanding of the topic. After we identified the common misconceptions the students possessed before the study by analyzing the coding of the pre-test, we started considering categories or levels of some sort to demonstrate students' conceptual understanding of angle.

After consideration of the data collected and the instruction used, we decided to use a modification of the Mitchelmore & White (2002) categories (See Table 1 and 2).

Table 1
The categories for angle as defined in Euclidean geometry.

Category	Definition
A0	Subject shows no comprehension of angle.
A1	Subject understands angle as a single fixed measurement.
A2	Subject understands angle as multiple fixed measurement, such as right, acute, obtuse or straight.
A3	Subject understands angle as an intersection of two lines, or two lines that meet as a point.
A4	Subject understands angle as a bending line with an array of measurements
A5	Subject shows a complete conceptual understanding of angle as defined in Euclidean geometry

Table 2
The categories for angle as defined by a rotation about a single point.

Category	Definition
B0	Subject shows no comprehension of angle as a rotation about a point.
B1	Subject understands angle as a single rotation about a point.
B2	Subject understands angle as a variety of rotations about a single point .
B3	Subject shows a complete conceptual understanding of angle as a rotation about a single point.

The scoring described above was used to compare students gain scores from the pre-test to the post-test. The scores were analyzed using statistical software to perform a paired *t*-test. A paired *t*-test was used to see if the means on these two normally distributed interval variables differ from each other. A paired *t*-test is used when you have two related observations (for example, two observations per subject, in this case pre-test and post-test) (Rao, 2007, p. 143). In each case, the null hypothesis was that the results of the pre-test and post-test were equal and the alternative hypothesis was that they were different. The results of the *t*-tests were used to see if either, or both, methods of instruction were beneficial to student learning of angle and if the learning with SCDs or TCDs were more beneficial. Finally, we analyzed if particular subgroups of students were supported differently by the two styles of DGS use.

Results

All of the students had been introduced to angle in earlier mathematics courses, but this was their first exposure in their current geometry course. Every student showed some knowledge of angle, which is evidenced considering 27 out of 27 (100%) of the students could either identify an angle within a variety of shapes, draw their own angle, or both. After analyzing the instructional activity, we analyzed each student's specific responses during three phases of the study: Pre-test & Basic Terminology, Classifications and Relationships, and Postulates & Post-Test. The categories in which the responses were given in each of the three phases are described in the methodology section and shown in Table 1 and Table 2. There were two different sets of categories, one for the definition of angle according to Euclidean geometry (A) and as a rotation about a point (B). None of the students in the SCD class mentioned angle as a rotation so category B was not used in this section of the analysis.

Looking at the students within each phase of the study demonstrated at which category the student's responses were in throughout the study. When analyzing the categories for the SCD class, we found that 4 out of 15 (27%) students showed an improvement of conceptual understanding of angle throughout the study. 7 out of 15 (47%) were categorized the same in the 1st and 3rd phase of the study, yet each had different results during phase 2. 4 out of 15 (27%) students' conceptual understanding of angle decreased as a result of the study. After analyzing the SCD class we went on to analyze the TCD class. 6 out of 12 (50%) students showed an enhanced conceptual understanding of angle throughout the study. 4 out of 12 (33%) were categorized the same in both the 1st and 3rd phase of the study, yet each had different results during phase 2. 2 out of 12 (17%) students' conceptual understanding of angle seemed to decrease as a result of the study. Only 2 out of 12 (17%) of the students mention the rotation of an angle and the sum of a single rotation being 360 degrees. After comparing the categorizations of both classes, the SCD class did not gain the level of understanding of angle needed to be in category A4 or A5. This along with the number of students who improved their level of understanding throughout the study shows the value of the TCD class. The TCD class seems to be more successful and this was shown with the results of the quantitative analysis.

A paired *t*-test was used to compare the difference between the pre-test score and the post-test score of each individual student from each class to determine if one method was more successful than the other. The null hypothesis of the paired *t*-test's performed in this study are assuming that there is no difference between the students' score on the pre-test and the post-test, $H_0 : \mu_d \leq D_0$. The alternative hypothesis is assuming that the use of the software did in fact affect the students' scores on the post-test in comparison to the pre-test scores for each of the different classes, $H_a : \mu_d > D_0$. After analyzing the results from the paired *t*-test for the SCD class, we were not able to conclude that the instructional activity improved the students' level of understanding at a 90% confidence level (p-value of .1159). However, the result from the gain scores (+1.53) does show that the instructional activity did improve their understanding, just not at a significant level. After analyzing the results from the paired *t*-test for the TCD class (+2.92), it is evident that the instructional activity did improve the student's level of understanding with a 95% confidence level (p-value of 0.0087). Therefore, both instructional activities are successful yet the TCD classes' improvement from the pre-test to the post-test was significant.

To answer the other research question about which methods were best for different groups, more quantitative analysis was done. Table 3 shows the results of the categorized groups of students: male vs. female, minority vs. non-minority, and sophomores vs. juniors.

Table 3

Group	Number of students	Average Gain Score	Significant at 95% confidence level?	Significant at 90% confidence level?	p-value
Female (SCD)	7	2.857	No	Yes	0.0701
Female (TCD)	8	3.429	Yes	Yes	0.0219
Male (SCD)	8	0.750	No	No	0.6955
Male (TCD)	4	5.000	No	No	0.1152
Minority* (SCD)	10	2.600	No	Yes	0.0559
Minority *(TCD)	10	2.400	Yes	Yes	0.0145
Non-Minority (SCD)	5	-0.600	No	No	0.5291
Non-Minority (TCD)	2	5.500	N/A	N/A	N/A
Sophomores (SCD)	11	2.273	No	Yes	0.0683
Sophomores (TCD)	9	3.667	Yes	Yes	0.0100
Juniors (SCD)	4	-0.500	No	No	0.7027
Juniors (TCD)	3	4.000	No	No	0.5286

*African American and Hispanic.

Discussion and Conclusion

This study was conducted to investigate DGS use in developing students' conceptual understanding of angle. Results show that the use of DGS was a significant aid for the students to gain insight into the concept of angle as defined by Euclid (1956). Additionally, a few students showed a better understanding of angle as a rotation and no students demonstrated a better understanding of angle in a curve. The software was an important teaching tool yet the SCD class struggled whereas the TCD class did not report a high level of difficulty using the software. It was more difficult for the SCD class due to the fact that they had to learn how to use the software while learning what the terms looked like in order to be able to construct the terms, whereas the TCD class did not need to be extremely familiar with the software to explore their instructional activity. Being unfamiliar with the software created some frustrations throughout the activity. Although, the software used in the study did have the drag mode, the SCD class was not as apt to use the drag mode. Therefore they demonstrated less conceptual understanding than the TCD class, which was totally dependent upon the drag mode. The pictorial representations created by the SCD students with the help of the software was beneficial, especially since some of the terms were completely new information to the students, as they had not covered it in previous mathematical courses. The pre-constructed diagrams the TCD class used to define the introductory terms helped them visualize and define the terms with the use of the software and its many features. Although each instructional activity had its own instructional advantages, according to the mean gain scores and the paired *t*-test conducted on the data the TCD group improved significantly where as the SCD group did improve, but not significantly.

As far as the subgroups, for each group of female students, the software was beneficial and significant in helping their understanding of angle but had little influence on the male students conceptual understanding according to their mean gain score from the pre-test to the post-test. Looking at the results from the *t*-test for the minority students for each group, one can see that the instructional activity was obviously beneficial for their understanding unlike the results from the non-minority students who did not improve as much. After analyzing the results from the *t*-test for sophomores and juniors it is evident that the sophomores improved significantly where the juniors did not. Therefore, the use of the software was more beneficial for the younger students of the class.

According to these results the pre-constructed diagrams were more beneficial for entry-level geometry students, which might not be the case for upper level students or adult learners using the software. This issue of pre-constructed diagrams vs. constructed diagrams needs to be researched for all ages because constructed diagrams have been proven important to the study and learning of geometry, yet for this age the pre-constructed diagrams were more apparent. In summary, the software was more beneficial for the TCD class than the student constructed class no matter if the student was male or female, minority or non-minority, or if they were a sophomore or a junior. Therefore, dynamic geometry software would be best used in the classroom with teacher-constructed diagrams with similar conditions as the study conducted at hand. More research is needed to answer this question definitively, yet for this study, and for other classrooms with similar dynamics, teacher-constructed diagrams were shown to be more advantageous to promote student conceptual understanding of angle.

TEACHERS' DEFINITION CONSTRUCTION: A STUDY BASED ON THE VAN HIELE THEORY

Janine M. Viglietti
University at Buffalo, SUNY
jv46@buffalo.edu

Deborah Moore-Russo
University at Buffalo, SUNY
dam29@buffalo.edu

This paper reports the results of analyses conducted to explore future and novice mathematics teachers' basic geometric knowledge of plane figures. Test scores suggest that teachers' responses to definition construction tasks often failed to include all necessary information to define a given figure. Other responses included redundant information and went beyond the information needed for a sufficient mathematical definition. Most teachers' responses corresponded to a van Hiele level of analysis, which aligns with national expectations for students in grades 3-5. Some teachers' responses were of the lowest van Hiele level, visualization, within which students should be operating in grades PreK-2.

van Hiele Theory and Geometry Instruction

The van Hieles' work to propose levels, as outlined in Table 1 below, for the acquisition of geometric knowledge is well known in the mathematics education research community (Fuys, Geddes, & Tischler 1988). As a framework, the van Hiele theory is useful when considering an individual's growth in geometric understanding (Malloy, 2002).

Level	Individual is able to…
Visualization	Focus on figures holistically; recognize and identify figures as general shapes
Analysis	Focus on the physical properties of figures; characterize figures by their attributes; describe the properties of figures.
Abstraction	Focus on the geometric properties of figures; order figures by their properties; interrelate properties and classes of figures using informal arguments.
Deduction	Focus on deductive reasoning; prove theorems deductively; establish relationships among theorems
Rigor	Focus on deductive geometry systems; establish theorems in different axiomatic systems; analyze and compare these systems

Table 1. van Hiele levels of thought

Researchers have shown that preservice and inservice teachers at both the elementary and secondary levels often are unable to operate at appropriate van Hiele levels for the material they are required to teach (Mayberry, 1983; Fuys, Geddes, & Tischler, 1988; Mason & Schell, 1988; Chappell, 2003; van der Sandt & Nieuwoud, 2003; Pandiscio and Knight, 2006). Concerns regarding preservice and inservice teachers' acquired van Hiele levels are not limited to the United States but rather seem to be a global problem (Gutiérrez, Jaime, & Fortuny, 1991; de Villiers, 1997; van der Sandt & Nieuwoud, 2003; Halat, 2008).

The National Council for Teachers of Mathematics (NCTM, 2000) in their *Principles and Standards for School Mathematics* have provided a cohesive vision for geometry instruction in the U.S. that involves expectations that students "analyze [the] characteristics and properties of two- and three-dimensional geometric shapes and develop mathematical arguments about geometric relationships" (2000, p. 41). According to the NCTM (2000) students are expected to perform tasks which reflect the increased cognitive sophistication typical of higher van Hiele levels as they progress through the Pre-K-12 curriculum.

In grades PreK-2 students are expected to operate at the *visualization* level. Students are encouraged to use their own vocabulary to describe geometric objects. By Grade 2, tasks typical of *visualization* level cognitive activity have evolved to include identifying and sorting shapes by similarities and differences. Such tasks hint at *analysis* level cognitive activity. In Grades 3-5 students are expected to operate at the *analysis* level. Students should develop more precision when describing shapes. The NCTM (2000) indicates that during these grades appropriate terminology is of increased importance as is the use of the "specialized vocabulary associated with the shapes and properties" under consideration (p. 165). In Grades 6-8 students are expected to operate at the *abstraction* level. By this time the interplay of properties should become evident to students allowing them to classify shapes into a hierarchy. Students should be capable of synthesizing their knowledge of the interplay of figural properties and the mathematical hierarchy to generate proper mathematical definitions. Initial *abstraction* level activities include investigating the diagonals of geometric figures and using observations to create alternate definitions for the figures under consideration. In Grades 9-12 the NCTM expects students to operate at the highest van Hiele level, *rigor*. Expectations include analysis of properties, making conjectures and using mathematical proof.

Considering national expectations that students' van Hiele levels should be increasing with grade level, it is reasonable to wonder if teachers possess the necessary knowledge to facilitate students' acquisition of higher levels of geometric reasoning.

van Hiele Theory and Definition Construction

As key components of geometric understanding (Sfard 2000), definitions and their construction allow insight into the depth of teachers' conceptualization of geometric figures. Research focusing on reasoning processes has related definition construction to the van Hiele theory. Gutiérrez and Jaime (1998) have identified four processes of reasoning in geometry: 1) *recognition* of types, components, properties, and families of figures; 2) *definition* of geometric concepts; 3) *classification* of geometric figures (or concepts) into different families; and 4) *proof* and ways of convincing regarding geometric figures and statements. Of the four processes, they further parse *definition* into *use of definitions* and *formulation of definitions*. In their 1998 work, Gutiérrez and Jaime offered a matrix with distinctive attributes related to their processes of reasoning (*recognition*, *use of definitions*, *formulation of definitions*, *classification*, and *proof*) that provide evidence that an individual is operating at one of the first four van Hiele levels[1]. Table 2 reveals the attributes for the formulation of *definitions* by van Hiele level offered by Gutiérrez and Jaime.

	Visualization	*Analysis*	*Abstraction*	*Deduction*
Formulation of definitions	Able to list physical properties of figure	Able to list mathematical properties of figure	Able to provide necessary and sufficient properties of figure	Able to prove the equivalence of definitions

Table 2. Distinctive attributes of the process of reasoning in each van Hiele level

Individuals operating at the *visualization* level often classify figures based on basic prototypes of those figures. Analysis of the properties of figures is absent; rather the individual views geometric figures holistically. This can lead to identification and classification of figures based on visual properties that are irrelevant (Burger & Shaughnessy, 1986) including descriptions using words like “pointy,” “round,” “skinny,” and “fat” (Clements et al., 1999; Gutiérrez & Jaime, 1998). Moving from *visualization* to *analysis* involves more than just acquiring new vocabulary to describe properties; it involves recognizing existing and new relationships between properties (de Villiers, 2010). At the level of *analysis*, individuals are able to use definitions; however they are likely to reject alternate definitions counter to the definitions they hold to be true (Burger & Schaunessy, 1986). Definitions constructed at this level are not restricted to sufficient properties (Gutiérrez & Jaime, 1998, Burger & Schaunessy, 1986). When asked to construct a definition, individuals are likely to make a long list of properties with no regard for redundancies (Gutiérrez & Jaime, 1998). Whereas *analysis* involves recognizing properties within figures, *abstraction* involves recognizing the interplay of those properties via logical relationships (de Villiers, 2010). Individuals working at the *abstraction* level understand the hierarchy of geometric figures and are able to recognize relationships among geometric figures. Mathematical activity at the *abstraction* level consists of interrelating and deducing properties within and among geometric figures (Adele, 1996). Individuals at this level are capable of constructing economical mathematical definitions (Burger & Schaunessy, 1986; Gutiérrez & Jaime, 1998), although some redundancy may be present if the relationship between properties is not immediately recognized as being related (Gutiérrez & Jaime, 1998). Individuals operating at the level of *deduction* are aware that definitions are arbitrary. They accept equivalent definitions and are capable of proving their equivalency.

Because definitions are the foundations of geometric understanding, the process of definition construction and the associated van Hiele levels are of paramount importance to the teaching and learning of geometry. It is critical that teachers have knowledge of geometric figures needed to construct definitions as well as the ability to operate at the level of *deduction*. Research in the past has utilized the van Hiele theory as a framework to explore teachers’ and students’ geometric understanding. The van Hiele theory has been used to reorganize curriculums in Soviet Russia in the 1960s and more recently in the United States (Adele, 1996; NCTM, 2000). Definition construction too has been considered a crucial component of the mathematics classroom (Mariotti & Fischbein, 1997; Sfard, 2000; Fujita & Jones, 2007). The van Hiele theory has had a strong influence on the course and scope of geometry instruction at an international level, coupled with the fact that definitions are a fundamental component of the teaching and learning of geometry, it is surprising that no single work has used the van Hiele theory to consider teachers’ responses to definition construction tasks. The goal of this work is to build upon prior research by exploring future and novice mathematics teachers’ basic geometric knowledge of plane figures. Teachers’ responses to definition construction tasks will be analyzed to determine both the completeness of their responses as well as the van Hiele level associated with their responses.

This work addresses the gap in the literature. The research explored novice and future teachers’ responses to 12 definition construction tasks. More specifically the goal was to answer the following questions.

1. Do teachers have the knowledge of planar figures needed to construct concise mathematical definitions? How many key components do future and novice teachers include when asked to create definitions for basic geometric figures?
2. In which van Hiele levels do teachers operate when constructing definitions for basic planar figures?

Methodology

Participants

The 21 participants (16 females and 5 males) in this study were students in a graduate-level mathematics education course during the fall 2009 semester at a large research university in New York State. Eleven were future teachers; all of whom had Bachelor's degrees and were taking graduate courses in order to fulfill state certification requirements for mathematics teachers. While some of the future teachers had temporary teaching experience, none had experience as a full-time classroom instructor. The remaining 10 participants were novice teachers, full-time teachers with up to three years of experience. These 10 novice teachers had Bachelor's degrees and the first level of state teacher certification in mathematics. Four of the novice teachers had prior experience teaching a secondary school geometry course, while one novice teacher was teaching geometry for the first time while taking the course.

Data Collection and Scoring

The data collection instrument for the study was a paper and pencil test with four components. The first component collected demographic information including prior coursework and teaching experience. The second component included items that addressed basic geometric figures. The third component included items that addressed geometric calculations, theorems, and proofs. The fourth and final component included items related to pedagogical decisions related to geometry instruction. The four components of the instrument were administered on the first day of the course as a pretest. This study analyzes the second section of the pretest, focusing on the teachers' responses related to definition and drawings tasks of basic planar geometric figures.

The teachers were instructed to give a written definition for each of the following figures in the order listed: circle, triangle, quadrilateral, vertical angles, isosceles triangle, rectangle, parallelogram, chord, kite, trapezoid, sector, and rhombus. These geometric objects will be referred to as figures throughout this paper. This research considered the teachers' written definitions.

A four-point rubric with values ranging from zero to three was developed to score the teachers' pretest responses. In general there were two to three components for each of the written definitions and sketched diagrams making the four-point scale most appropriate. The scores for each level of the scale for the teachers' written definitions follow.

0 *Incorrect*: Blank, incorrect, or irrelevant response; response yields no real conceptualization of geometric figure; all key components are missing

1 *Mostly incorrect*: Incorrect, or limited correct information is given however two key components of the definition are missing

2 *Mostly correct*: Partially correct information is given however one key component of the definition is missing

3 *Correct*: Complete, correct response all key components of the definition are present

The second rubric used to analyze the data assessed the teachers' responses to the definition construction task and assigned a corresponding van Hiele level. The nature of a definition task involving geometric figures is such that it can reveal information only as high as *abstraction* level cognitive activity. In order to assess cognitive activity at levels higher than *abstraction* one would need to include tasks that involve deductive reasoning such as determining the equivalence of multiple definitions. Since such tasks are outside the scope of this investigation, the rubric has a maximum value corresponding to the level of *abstraction*. The rubric employed in this study was based on Gutierrez and Jaime's (1998) work related to definition construction processes (see Table 2). The rubric was scored using integer values from 0 to 3 as shown below. Examples for each level are provided in Table 3.

0 Provided no definition or a definition with irrelevant/incorrect information
1 *Visualization*: Provided a definition based on the physical properties of the figure
2 *Analysis*: Provided a definition that listed the mathematical properties of the figure
3 *Abstraction*: Provided a definition based on a set of necessary and sufficient properties of the figure

Teacher	Definition for Rectangle	Scoring Rationale	Score
A	A quadrilateral w[ith] 2 distinct sets of congruent sides	Definition is incorrect, exhibits signs of hierarchical classification error	0
B	A figure with 2 sets of opposite sides which are parallel. 1 pair of sides are equal. The other pair are also equal but not the same as the first pair	Definition is based on a prototypical image of the figure	1
C	A closed figure consisting of four line segments with the following conditions. • 4 rt [angles] • 2 pairs of opposite sides $\parallel$ • 2 pairs of opposite sides $\cong$	A list of mathematical properties is given	2
D	A parallelogram whose diagonals are $\cong$	Necessary and sufficient conditions are given with minimal to no redundancy	3

Table 3. van Hiele level sample responses for rectangle definition construction task

Results

The grand mean for the teachers' scores on definitions was 2.31. As mentioned above, a rubric scale value of 3 indicated that the definitions were complete whereas a mean score of 2 indicated that a teacher's response was missing a key component on the majority of the definitions. Mean scores of 1 indicated very little demonstrated understanding of the twelve figures present on the pretest.

Assuming interval level measurement, mean scores for the teachers' responses to the definition tasks ranged from 1.00 to 3.00 with a grand mean of 2.31. Nine of the 21 teachers' responses to the definition tasks had mean scores between 2.50 and 3.00, nine of the teachers' responses had mean scores between 2.00 and 2.50, and three teachers' responses had mean scores between 1.00 and 2.00. For measures of dispersion standard deviation values ranged from 0.00 to 1.35. Six of the 21 teachers' responses resulted in standard deviation values greater than 1.00. One teacher in particular received the highest possible scores on some items and lowest possible scores on others.[3]

The teachers' responses to the definition tasks for three figures were assigned mean and median rubric values of 2 or less. Two teachers did not respond to the chord definition task (M = 1.95, SD = 1.16; Mdn = 2, IQR = 2). One teacher referred to a personal concept image indicating

[3] Interval and ordinal descriptive statistics supported each other; however, more precision was evident when using mean scores. For the sake of brevity means scores are reported.

that a chord was "a combination of notes…" These three teachers' were assigned scores of 0. Teachers who were assigned scores of 1 or 2 for their responses most often referred to the chord as a line rather than a segment, or disqualified the diameter as a special case of the chord.

Two teachers did not respond to the kite definition task (*M* = 1.33, *SD* = 1.11; Mdn = 1, IQR = 1). Three teachers referred to a personal concept image. One teacher referred to a kite as "a recreational item used in high wind," another said "something you fly," and a third said "a diamond shaped polygon." Another teacher simply wrote the word "rhombus." These six teachers did not indicate and of the key components of the figure and were assigned scores of 0. Those teachers who were assigned scores of 1 or 2 for their responses to the kite definition task most often described the figure in terms of the parallelism of opposing sides or congruence of angle measurement. The key component of congruency of adjacent sides was absent in these responses.

Two teachers did not respond to the sector definition task (*M* = 1, *SD* = 0.95; Mdn = 1, IQR = 1). Two teachers referred to a personal concept image. One teacher referred to a sector as "a section of a vector," and another said "in business, it is used to explain that the office building is split into sections." These four teachers' responses were assigned scores of 0. Although a sector refers to the region enclosed by two radii and an arc of a circle, the remaining teachers whose responses were scored 0 most often believed that sector referred to bisection of a figure like a rectangle. Those teachers who were assigned a score of 1 indicated that the sector was the region bounded by a circle and a chord. Three teachers indicated that sector dealt with the perimeter of a circle rather than its area. One of these teachers referred to a sector as "a[sic] arc or line between two points," and another wrote "a piece of the circumference of a circle." These teachers were assigned scores of 2 as they included two key components the center point and radii.

The grand mean for the van Hiele level assigned to the teachers' responses for the definition tasks was 1.58 with no teacher's responses to the definition tasks resulting in mean values at a level of *abstraction*. A mean or median van Hiele level value of 3 indicated that a teacher' responses to the 12 definition tasks contained only those conditions that were necessary and sufficient to define the figures. In contrast values of 2 and 1 for a given figure indicated that some of the teacher's responses were *analysis* level or *visualization* level or both. *Analysis* level definitions and drawings included lists of the properties of the 12 figures while *visualization* level definitions were based on prototypical versions or the physical properties of the 12 figures.

For interval measures mean values for the teachers' responses to the definition task ranged from 0.33 to 2.67. Six of the 21 teachers' responses to the definition tasks had mean values between 2.00 and 2.67 corresponding to a level of *analysis*. Fourteen of the 21 teachers' responses received values between 1 and 2 corresponding to a level of *visualization* for the definition tasks. One of the 21 teachers' responses received a mean value of 0.33. For measures of dispersion standard deviation values ranged from 0.49 to 1.44. Twelve of the 21 teachers' responses resulted in standard deviation values greater than 1. For many teachers low values assigned to responses to the chord, circle, kite, and sector definition tasks resulted in larger spread.[2]

Discussion

Despite the fact that all of the teachers in the study had extensive mathematical coursework in their undergraduate degrees, their results on the pretest were unimpressive. It was hypothesized that the definition tasks would pose no difficulty for the teachers due to the basic nature of the 12 figures under consideration. The expectation was that the teachers would receive scores at or near the highest assessable score, a rubric score of 3; however, the grand mean for the teachers' responses to the definition tasks was $M = 2.31$. Results suggest that most teachers were missing one key component according to the scoring rubric. Mean scores by teachers for definitions provide evidence that many teachers' definitions were incomplete with ninety-five percent of the teachers scoring less than 3. Fourteen percent of the twenty-one teachers scored less than 2 indicating that their definitions were missing more than one key component. Many teachers demonstrated trouble recalling the components of the geometric figures in their definitions.

These low scores are attributable in large part to incomplete knowledge of the figures. These results suggest that the teachers in this study did not possess knowledge of geometric figures sufficient to teach the material indicated in the New York State Education Department's (2005) Learning Standards for Mathematics or the NCTM's (2000) PSSM document. Results support researchers' claims that there are deficits in teachers' content knowledge (Chappell, 2003).

Overall scores for definitions provided additional evidence that many of the teachers' definitions were not at a level appropriate for the coursework that they would be expected to teach. The teachers' responses to the definition task corresponded to low levels on the van Hiele model. Most teachers' definitions corresponded to *analysis* and were appropriate for grades 3-5 expectations according to national standards. Some teachers' responses aligned with the lowest van Hiele level, *visualization*, and were appropriate for grades Pre-K-2 according to national standards.

Recent curricular revisions in New York State, as well as suggested revisions in other states (e.g., Georgia), have brought a sharper focus on geometry content in the curriculum. This renewed focus on the geometry curriculum reminds us how important teachers' geometric knowledge is. The ability to define, and to do so with an awareness of what it means to define, is a critical component of effective instruction in geometry. Although the sample size in this study is limited and any attempt to extend these finding to a broader audience should be done with extreme caution, the data presented here are a platform for further exploration of teachers' knowledge of geometric figures, in general, and definition construction, in particular. Future work will address the use of the van Hiele theory to explore teachers' use of multiple representations when considering geometric figures.

Endnotes

1. Gutiérrez and Jaime (1998) purposely omit the *rigor* level indicating that they do not include it because its existence has not been confirmed. Level 4, rigor, is outside the scope of this research so its absence is of little import.
2. As with scores, the ordinal and interval statistics for van Hiele level values supported each other.

AUTHORING MATH: MATHEMATICS LEARNERS AS BRICOLEURS

Alayne Armstrong
University of British Columbia
armstrg@interchange.ubc.ca

This paper proposes that groups of middle school students who pose sub-problems as they solve open-ended mathematics problems might be considered to be "authoring" their mathematics. Using a definition of authoring as "the means through which a learner acquires facility in using community validated mathematical knowledge and skills"(Povey et al, 1999, p. 232) and of bricolage as a negotional form of reasoning, this paper argues that through problem posing students become bricoleurs, making discoveries by reassembling what they already know. In doing so, they create a storyline through their actions and ideas, in effect, becoming authors of their own mathematics.

Introduction

> *Mathematical work does not proceed along the narrow logical path of truth to truth to truth, but bravely or gropingly follows deviations through the surrounding marshland of propositions which are neither simply and wholly true nor simply and wholly false (Papert, 1980, p. 195).*

As a middle school teacher, I've found myself straddling the divide between mathematics and the humanities, teaching both math and English as my major subjects rather than the usual combination of math and science. One of the ways I've bridged this divide is through Problem of the Week (POW) (Tsuruda, 1994) assignments. Students are presented with a rich mathematics problem and given class time, and the opportunity to choose their own groups, to work on their ideas before composing a written account of their reasoning. They have quickly learned that the problems require thought, and can be solved in different ways. Despite the groaning that inevitably occurs whenever I announce it is time for another POW, at the end of each year when I survey students about what has gone well (or poorly) for them in math class, POWs are often highly rated. Although the questions are "hard," students often report that they like the challenge, the different kinds of math that they explore, but most of all, they are proud of their work. There is a sense of ownership similar to what I observe during English class when they share their creative writing with their peers. What is going on?

For my master's research, I had used my students' work on POW to consider the phenomenon of group flow. Looking at the transcripts again a few years later, it struck me that each of the groups that I considered to be functioning well (i.e. on task and working together) were asking questions – posing sub-problems as it were – about the POW as they worked towards an overall solution. This problem posing appeared to be a way of making the POW their own, of framing the mathematics in their own way.

Recalling my own experiences with English literature, it occurs to me part of the pleasure of being an author comes from the little conflicts you set for your characters and watching how their resolution serves to drive the main plot. Consider "classic" storylines that recur time and time again. Shakespeare's central problem of "star-cross'd lovers" in *Romeo and Juliet* is echoed in our contemporary *West Side Story* and even the more recent *High School Musical* – and Shakespeare's play itself is a descendant of Arthur Brookes' 1562 poem *The Tragicall Historye* *of Romeus and Juliet,* which is itself a translated interpretation of one of Bandello's Italian short stories *Novelle* (Drabble, 1985). Yet each author has made the storyline his/her own. While the overarching problem is the same (young couple from warring worlds come to a tragic end), it is how the smaller problems, or conflicts, are settled that makes each text unique. Might the same be said of middle school math? While the students are unlikely to develop ground-breaking theorems, there is much that is worthwhile to be drawn from playing around within the parameters of a larger problem and, in doing so, finding their own path through it. Could what the POW groups were doing in their problem posing be considered to be authoring in math? And might authoring be a way for students to be a part of the larger math community, to do math rather than to have math done to them?

The Art of the Bricoleur

The bricoleur "derives his poetry from the fact that he does not confine himself to accomplishment and execution: he speaks not only with things…but through the medium of things" (Lévi-Strauss, 1966, p. 21).

The central issue in this paper is: are we so conditioned to expect the act of mathematizing in school to proceed in a certain abstract formalized way that we are neglecting other ways in which mathematical understanding may emerge?

Papert is one thinker who has touched on this issue in his consideration of *bricolage* as a method students use when exploring geometrical concepts with computer tools (LOGO). Bricolage is a term that originates from Claude Lévi-Strauss's anthropological work *The Savage Mind* (1966). In it he contrasts what he considers to be the analytic method of scientific theorizing of the Western world, with the more concrete theorizing, or bricolage, employed in other more "primitive" cultures. He writes:

> The "bricoleur" is adept at performing a large number of diverse tasks; but, unlike the engineer, he does not subordinate each of them to the availability of raw materials and tools conceived and procured for the purpose of the project. His universe of instruments is closed and the rules of his game are always to make do with 'whatever is at hand', that is to say with a set of tools and materials which is always finite and is also heterogeneous because what it contains bears no relation to the current project, or indeed to any particular project, but is the contingent result of all the occasions there have been to renew or enrich the stock or to maintain it with the remains of previous constructions or destructions. (Lévi-Strauss, 1966, p. 17-18)

While the "engineer" carefully plans ahead and gathers the specific tools required before the project begins, the bricoleur does what he/she can with what is immediately available.

Some have argued that bricolage is an inferior form of reasoning, although not one limited to particular cultures as Lévi-Strauss appears to suggest (Berry & Irvine, 1986). In teaching, for instance, the bricoleur teacher borrows and uses old teaching methods and resources without improving them, resulting in pedagogical inadequacies (Hatton, 1989). In a slightly less negative view, bricolage is depicted as a method teachers are forced to fall back on due to working conditions – without enough time or resources to engage in proper planning, the bricoleur teacher ends up gathering lesson and unit plans from here and there in order to get by (Scribner, 2005).

These interpretations of bricolage as just wholesale "borrowing" are too simplistic. A teacher using another's lesson plan may be using what's on hand, but in doing so he/she is "reinventing based on evolving intentions" (Reilly, 2009, p. 383) and the results may be far different from the purpose of the sources. Although original meaning is sedimented in the artifact being used, because these artifacts are being recombined with other ones, the resulting connections develop into new codes of meaning (Barker, 2004). One can see this, for instance, with fashion (Harajuku, a Japanese street style that mixes, for instance, traditional Japanese attire with modern Western wear), or with writing (punk writer Kathy Acker's *Great Expectations* which "plagiarizes" heavily from Dickens's novel of the same name but to a much different effect). Bricolage, then, has the potential to be both creative and subversive.

Papert suggests that learning is itself bricolage:

> The process reminds one of tinkering: learning consists of building up a set of materials and tools that one can handle and manipulate. Perhaps most central of all, it is a process of working with what you've got. We're all familiar with this process on the conscious level, for example, when we attack a problem empirically, trying out all the things that we have ever known to have worked on similar problems before. But here I suggest that working with what you've got is a shorthand for deeper, even unconscious learning processes (1980, p. 173).

In a later study of computer programming students, Turkle and Papert define bricolage as "a style of organizing work that invites descriptions such as negotiational rather than planned in advance" (1990, p. 144). Working from Piaget's theory of intellectual development, although rejecting the hierarchy of his proposed stages, the authors characterize the engineer, who they call the "planner," as having a "formal" method as compared to the bricoleur who uses a "concrete" method. In comparing these learners, they write:

> The bricoleur resembles the painter who stands back between brushstrokes, looks at the canvas, and only after this contemplation, decides what to do next. For planners, mistakes are missteps; for bricoleurs they are the essence of a navigation by mid-course corrections. For planners, a program is an instrument for premeditated control; bricoleurs have goals, but set out to realize them in the spirit of a collaborative venture with the machine. For planners, getting a program to work is like "saying one's piece"; for bricoleurs it is more like a conversation than a monologue. In cooking, this would be the style of those who do not follow recipes and instead make a series of decisions according to taste. While hierarchy and abstraction are valued by the structured programmers' planner's aesthetic, bricoleur programmers prefer negotiation and rearrangement of their materials (1990, p. 136).

I quote this passage at length because it highlights important aspects which I will discuss further later, namely: the importance of mistakes as "mid-course corrections", the contemplation that takes place during the work process, and the characterization of it being "more like a conversation than a monologue" involving a negotiation and rearrangement of ideas. This, I believe, describes in part how a small group works. However, what tends to be privileged in mathematics classes is the more formal thinking that underlies the planner's process, the abstract reasoning that theorists like Piaget see as evidence of a later more mature stage of development. Turkle and Papert (1990) argue, however, that formal and concrete reasoning are not different stages of development, just different styles of organizing work.

Mathematics as Bricolage

That mathematics is largely perceived in North American schools as a timeless truth, external to human existence should be no surprise. There is a long tradition in Western thought stretching back to Plato and his ideal forms, of mathematics as an eternal absolute, and that it is only through thinking and theorizing by an elite group (i.e. mathematicians) that its laws and axioms can be uncovered. Lakoff and Nuñez call this "standard folk theory of what mathematics is for our culture" (2000, p. 340) the Romance of Mathematics, and they argue that its influence has had a number of negative effects:

It intimidates people, alienates them from math, maintains an elite and justifies it. It rewards incomprehensibility, and this inaccessibility perpetuates the romance. The alienation and inaccessibility contributes to the division in our society of people who can function in an increasingly technical economy and those that can't – social and economic stratification of society (2000, p. 341).

In the past century, however, an alternate view of mathematics has arisen – that of mathematics as a human invention that has been developed and refined by various societies throughout history. Lakatos, the philosopher who first set this idea out clearly (Ernest, 1998), argued for what he called "quasi-empiricism" in his *Proofs and Refutations* (1976). Here mathematics is not portrayed as static Platonic form that is discovered, but as a process, an evolving aspect of culture. The conversation between teacher and students as they discuss the Euler characteristic at first seems to be a Socratic dialogue where the teacher is apprenticing his students into traditional conventions of proper mathematical arguments. However, the alternative narrative provided by the footnotes undermines this interpretation, showing how "acceptable" mathematical strategies have varied during different eras of history, and pointing to an analogy between political ideologies and scientific theories (Lakatos, 1976, p. 49). Returning to the main storyline of the book, it becomes clear from the characters' arguments that the process of refining a mathematical proof is never-ending. There is always something else to consider. In the working, and reworking of Euler's axioms, Lakatos illustrates how mathematics is produced through a process of bricolage.

Authoring in Math

As math evolves, an invented tapestry of concepts, problems and invented rules is passed along in the community. Yet, even as an invention, mathematics is still largely presented to the general public as one unattached to any names or faces, ahistorical as it were. Unlike science, where Newton supposedly discovers gravity after being hit on the head with an apple, and Galileo defies the Church in his support of a heliocentric view of the universe, math has few founding stories. We can point to "the ancient Greeks," and maybe associate one particular ancient Greek (Pythagoras) with a hypotenuse, but there is little else to link math to the popular imagination. "The human meaning-making has been expunged from the accounts of mathematics that appear in standard texts; the contents are then portrayed in classrooms as authorless, as independent of time and place…. Mathematics becomes a cultural form suffused with mystery and power" (Povey *et al*, 1999, p. 235).

As a result, school mathematics is perceived by many students to be a series of rules imposed by an outside source, be it textbook or teacher, with little recognition that human thinking, even student thinking, generates math. "All the mathematical methods and relationships that are now known and taught to schoolchildren started as questions, yet students do not see the questions. Instead, they are taught content that often appears as a long list of answers to questions that nobody has ever asked" (Boaler, 2008, p. 27). And there are many teachers continue to present math as a set of rules and conventions, and to perceive math education as the indoctrination of their pupils into this long list of answers.

The concept of *authoring* math struggles against this sense of mystery. Brown (1996) suggests that, as the focus of math educators turns more to math activities rather than to the mathematics itself, interpretation plays far greater a role – for instance, the students' understanding of a mathematical situation, and how their interpretation changes as they notice new aspects of the situation and make new connections. This emphasis on interpretation, Brown argues, is similar to Gadamerian hermeneutics in that the meaning of the mathematics arises from the activity and the language used to frame it. And in that sense, it opens up the possibility of authorship to any of us who choose to engage in mathematics and communicate our interpretations to others. Mathematician Jonathan Borwein writes, "we respect *authority*, but value *authorship* deeply however much the two values are in conflict. For example, the more I recast someone else's ideas in my own words, the more I enhance my authorship while undermining the original authority of the notions" (2006, p. 3).

Povey *et al* (1999) define *authoring* as "the means through which a learner acquires facility in using community validated mathematical knowledge and skills" (p. 232). They use the term *author/ity* to play with the concept of *authority* – the traditional view of mathematical knowledge as external, fixed and absolute – splitting up the word to foreground the idea of there being an author (or authors) behind the scenes who negotiates and creates this knowledge. In this scenario, they write, "teachers and learners… work implicitly (and, perhaps, explicitly) with an understanding that they are members of a knowledge-making community.... As such, meaning is understood as negotiated. External sources are consulted and respected, but they are also evaluated critically by the knowledge makers, those making meaning of mathematics in the classroom with whom *author/ity* rests" (Povey *et al*, 1999, p. 234). In a knowledge-making community students are aware of the fact that someone did author the math in the books around them, and that in their work as bricoleurs they too are part of this authoring tradition. This helps to demystify math, and to alleviate students' fear of the subject. As well, not only does the notion of author/ity foster a more equal relationship between learners and teacher, but it also gives responsibility to the students to break away from the role of passive empty vessels waiting to be filled with facts, and instead make meaning of mathematics for themselves.

Problem Posing as Pushing the Story Along

In math, problem posing can be defined as both "the creation of questions in a mathematical context and to the reformulation, for solution, of ill structured existing problems" (Pirie, 2002, p. 929). One might say there are two kinds, depending on the purpose of the problem being posed (Silver, 1994), and where it occurs in relation to the problem solving process – i.e. when during the mathematical story process you happen to enter.

If you walk into the story outside of the problem solving process, either before it has begun, or when it is finished, the problem posing has the purpose of *problem formulation*, or "What new problems are suggested by this situation, problem or experience?" (Silver, 1994). Here the problem is generated from the situation itself, perhaps using techniques such as "what-if-not" (Brown & Walters, 2005). Silver (1994) suggests that it also occurs after a problem has been solved, akin to Polya's "look back and reflect" stage, to consider any new situations or problems that have arisen. Others disagree, arguing that "working from situations… is not the same as working from problems. Part of the activity is, in fact, the formulation of [local] problems that may arise out of definitions and rules that are developed in the discussion of the situation"

(Banwell, Saunders and Tahta, 1972). Perhaps the difference in these points of view is between creating a story based on your experiences of what's around you, and being inspired by the plot of another's story to develop your own.

If you walk into the middle of the story, while problem solving is occurring, problem posing takes the form of *problem reformulation,* or: "How can I (re)formulate this problem so that it can be solved?" (Silver, 1994). Here a related problem is generated in response to the original problem, as a way of making that original problem more accessible (Polya, 1957). This could take the form of modifications (Whitin, 2004), perhaps rewording the original problem, or setting it in a more accessible context, so that it can be directly solved. It could also take the form of purposely extending the original problem (Whitin, 2004) to see what else there is to investigate. Finally, problem reformulation might occur through the creation of sub-problems that are produced as one pursues the original problem, as a way of breaking the original problem up into more digestible pieces, or of dealing with situations that need to be resolved before the problem itself can be tackled. Despite what on the surface may seem a very pragmatic way to go about solving a problem, this reformulation is a creative process with the evolving problem taking on a life of its own (Kilpatrick, 1987):

Duncker (1945) offered the insight that each stage of the solution of a problem constitutes the problem's reformulation. Thus the mediating phases provide opportunity for problem-posing along the way. These re-formulations are products of creative thought. Finding and posing the problem is the critical outer layer of the problem solving process. Once that layer is peeled away, it reveals further layers within which new problems reside problems that must be addressed as steps in the finding of a grand solution (Lewis, Petrina & Hill, 1998).

Just as a literary story is propelled along through a series of unanswered questions, so too is a mathematical story. In describing how painters work, Sawyer notes that some artists have an improvisational style called *problem-finding* by creativity researchers, one which involves "constantly searching for her or his visual problem while painting" (2000, p. 153). He then argues that "[a]n improvisational theater performance is also, of necessity, a problem-finding process – albeit a collective one, akin to a brainstorming session" (2000, p. 154).

Improvisational theory is helpful in framing the interaction involved in these communications, "provid[ing] a means to characterize this process [the notion of self organization fundamental to the emergence of the collective] and offer[ing] a way of pointing to the conditions under which the collective might grow and develop" (Martin, Towers & Pirie, 2006, p. 159).

The nature of human behavior itself is improvisational:

> (T)o be thinking what he is here and now up against, [someone] must both be trying to adjust himself to just this present once-only situation ***and*** in doing this to be applying lessons already learned. There must be in his response a union of some Ad Hockery with some know-how. If he is not at once ***improvising*** and improvising ***warily,*** he is not engaging his somewhat trained wits in a partly fresh situation. It is the pitting of an acquired competence or skill against unprogrammed opportunity, obstacle or hazard. It is a bit like putting some ***new*** wine into ***old*** bottles (Ryle, 1979, p. 129).

Thanks to the popularity in recent years of improvisational groups such as Second City, and television shows like *Whose Line is It Anyways*, "improvisation" has become synonymous with spontaneity in North American popular culture. However as Ryle points out, with ad hockery comes know-how, and what is new is based on the old. It is, in this sense, a form of bricolage that recombines and reworks old ideas into new patterns. There is both structure and the freedom to work with/within that structure.

In an interview with musicologist Paul Berliner (1994, p. 66-71), jazz musician Lee Konitz suggests that there is a range of behaviours that can be considered improvisational, depending on the proportion of structure to spontaneity, a concept Weick terms “full spectrum improvisation” (1998). On the most rigid side of the spectrum (“Interpretation”), there is little change from the original structure. In jazz, this occurs when a song is performed and the musicians play all the notes in the original order, but they stress them differently in order to create their own interpretation. In theatre, the players follow the script, saying all of the words in the correct order, but they use their voices and make gestures to provide their own interpretation of what the written text means. An interpretation in a mathematics class might occur when students are first learning to work with example spaces (Watson & Mason, 2005). They are provided with an example (e.g. ½) and then asked to generate more on their own (e.g. 0.5, 4 ÷ 8, ¼ + ¼, etc). Interpretation, then, is like following a path through the woods – you can walk, you can skip, you can run, you can do a series of somersaults, but you keep to the constraints of the path.

At the other end of the spectrum (“improvision”) there is the potential for complete transformation. The song provides a starting point but parts of the melody are changed, or completely replaced, to such an extent that the resulting song does not resemble the original. In theatre, the actors may start with Cinderella, but then surround her with other characters (Superman, Jay Leno, etc.), strand them on a desert island, note that it’s Thanksgiving, and take it from there, throwing in other ideas and characters, and changing or removing others as the story moves along.

It is at this end of the spectrum that I propose mathematical problem posing belongs. “The learner becomes a *bricoleur* who assembles new things from old. In the process, an idea for an entirely new object may arise, leading to new mathematical questions, new exploration, and possibly revision of previous ideas” (Watson & Mason, 2005, p.157). In each of these cases, it is only when the performers/students look back that they can discern a pattern, or storyline, to their actions and ideas: “The improvisational process is one of laying a path down in walking” (Montuori, 2003, p. 246). It is through the laying down of this path that students become authors of mathematics.

THE RELATIONSHIP BETWEEN TEACHER PEDAGOGICAL CONTENT KNOWLEDGE AND STUDENT UNDERSTANDING OF INTEGER OPERATIONS

Sarah J. Brasiel
Edvance Research, Inc.
sbrasiel@edvanceresearch.com

This study examined whether professional development (PD) related to integers improved pedagogical content knowledge (PCK) of teachers. The three week program involved 22 teachers and 341 grade 8 students from an urban district. The teachers and students explored a comprehensive representation for integers using vectors on a number line and engaged in argumentation about strategies for modeling integer operations. The results showed significant growth in teacher PCK following the PD and a significant association between teacher posttest PCK and student improvement in understanding even when controlling for years of teaching experience, teacher pretest knowledge, and student pretest knowledge.

Improving student understanding of integers and operations with integers is important for many educators; however, there is not one instructional model for integer operations that seems satisfactory in explaining all integer operations. Integers are the set of positive whole numbers, negative whole numbers and zero. Integers are a number and operations concept that is foundational in mathematics, and used in applications in other fields such as science, business, and statistics. However, students struggle with this foundational concept, particularly around negative numbers (Ryan & Williams, 2007).

Introduction

The mathematics education community has struggled to find an instructional model that effectively supports students in constructing a rich conceptual understanding of integers and of negative numbers, in particular. Such a model would need to address the purpose of the negative numbers and justify the arithmetical operations on them in order to be comprehensive. The following models are commonly used in classrooms K-8: Annihilation model with counters or chips, movement on the number line; transformations of an object's position and state (Schwarz, Kohn, & Resnick, 1993/1994); elevator or elevation model ; use of metaphors for example, people getting on and off a bus; technology, such as, calculators and virtual manipulatives; and other real world applications, to name a few, money, temperature, and yardage in football.

These models lack the comprehensiveness needed to address all operations with negative numbers (Fischbein, 1994). Due to the lack of a comprehensive instructional model, many students struggle with understanding integers and integer operations, developing misconceptions about these numbers (Ryan & Williams, 2007). This study is a step towards developing an effective and comprehensive instructional model using a number line vector representation along with professional development (PD) for teachers to build pedagogical content knowledge (PCK) focusing on engaging students in classroom discourse through argumentation.

Theoretical Framework

Teaching mathematics is a complex profession which requires more than just knowledge of the subject matter. According to Fennema and Franke (1992), the components of mathematics teachers' knowledge include the following: knowledge of mathematics, knowledge of mathematical representation, knowledge of students, knowledge of students' cognitions, and knowledge of teaching and decision making. Mathematical representations play an important role in helping students connect abstract mathematics into something they can understand. Some researchers have focused on developing what is referred to as pedagogical content knowledge (PCK). Grouws and Schultz (1996) include in their description of PCK the ways teachers provide students with useful unifying ideas, clarifying examples and counter examples, helpful analogies, important relationships, and connections among ideas. This interpretation includes more of the behaviors of teachers rather than just the types of knowledge they possess.

The theoretical framework for this study is informed by research on the relationship between teacher PCK and student learning. Turnuklu and Yesildere (2007) in their research of PCK in mathematics of 45 pre-service teachers in Turkey and their approaches to teaching fractions, decimals, and integers, found that many of the pre-service teachers had difficulty understanding student misconceptions related to integer operations, facilitating mathematical discussions that would engage students in mathematical thinking about integers, and asking questions to assess student understanding. Their work was informed by the research of An, Kulm, and Wu (2004) which they used to construct the following theory: (a) PCK is associated with teacher beliefs, content, knowledge and how one teaches, (b) teaching is associated with PCK and knowledge about students' thinking, (c) knowledge about students' thinking is associated with addressing students' misconceptions, engaging students in math learning, building on students' ideas, promoting students' thinking about mathematics, and (d) student learning is most closely associated with knowledge about students but due to the interrelationship of the model, student learning is associated with all of the four components.

This integrated approach of improving teacher PCK, developing the ability of teachers to facilitate conversations about mathematics among students in their classrooms, and the resulting student conversations, I propose, is vital to improving student learning. There is growing evidence that students in elementary, middle, and high school can reason, justify their thinking, make claims and warrants in a supportive classroom that is a mathematical community (e.g., Enyedy, 2003; Francisco & Maher, 2005; Goos, 2004; Mueller & Maher, 2009). However, developing this kind of environment requires expectations for behavior, norms for making claims and warrants, activities that promote different ideas, and facilitation of the development of reasoning through teacher questions to advance student thinking (McCrone, 2005).

Most mathematics teachers are familiar with mathematical reasoning, but formal reasoning is often reserved for students in high school when they are taught how to construct proofs as mathematical arguments using accepted statements considered facts such as definitions and theorems established by the mathematical community. They learn the acceptable form of justifying their thinking in the proof format expected by their teacher or the textbook. However, Stylianides (2007) and Francisco and Maher (2005), argue that this concept of mathematical proof can occur as early as elementary school where students are given opportunities to reason and justify their thinking. Students and teachers can collaborate to establish classroom norms for what is acceptable for a proof in their class community. These experiences can be important prerequisites for future work with more formal mathematical proofs used by participants in the larger mathematics community to communicate to other mathematicians.

Therefore, I determined that mathematical reasoning using argumentation would be an age appropriate activity for students in this study. My hypothesis was that teacher understanding of integer operations would improve by exposing them to activities that apply integers in real world contexts related to vector forces and temperature change and activities that explore integer operations using a number line. I also hypothesized that teachers would be enabled to facilitate student argumentation around misconceptions after experiencing their own use of argumentation around misconceptions and solution strategies and creating structures for their classroom to facilitate argumentation. Finally, I proposed that student understanding of integer operations would improve when they were provided with opportunities to engage in classroom discourse and argumentation about doing mathematics, which would be evident by improved performance on a posttest compared to the pretest. Specifically, the following research questions were investigated:

- What are the general patterns of teacher content and pedagogical knowledge of integers based on responses to a pretest and posttest?
- To what extent does PD impact teacher content and pedagogical knowledge as measured by growth between pretest and posttest?
- Is there a significant difference between the growth between students' pretest and posttest scores for 2010 compared to the growth made by students in 2009?
- Do differences in teacher content and pedagogical knowledge explain more of the variance in student performance than years of teaching experience of a teacher?

Methods

This research was conducted during a three-week summer program for grade 8 students in a large urban school district in Central Texas. This program serves students who had not passed the state mathematics assessment, Texas Assessment of Knowledge and Skills (TAKS) test, required for promotion to high school. Each year, program administrators are challenged to find teachers to teach in the program. Most of the teachers participate in summer school, so few remain that are available or interested in teaching in this program. Each year there have been several first year teachers teaching in the program. There is a need to ensure that the teachers understand the mathematics in the curriculum activities in the program as well as understand common misconceptions that students may have by including PCK features in the PD for the program.

Participants

There were 341 students and 22 teachers in the summer program. Twenty-one of the 22 teachers attended the PD and consented to participate. The age of the teachers ranged from 21 to 63 years with an average age of 34 years. Sixty-two percent of the teachers were female. The average years of teaching experience for these teachers was 7 years (ranged from 1 to 31 years). There were 24 percent of the teachers with a masters' degree and only 10 percent with an undergraduate major in mathematics. Thirty-eight percent had previously taught in this summer program which started the summer of 2008.

Intervention

This research study was considered an intervention that supplemented the current PD that had occurred in the past two years with additional emphasis on the development of teacher PCK related to integers, rather than just exposure to the student activities as was done previously. The six hours of PD that constituted the intervention for this study focused on improving teacher understanding of integers and integer operations. During the PD, the teachers read a chapter from *Children's Mathematics 4-15: Learning from Errors and Misconceptions* by Ryan and Williams (2007) entitled "Children's Mathematical Discussions." The discussion among the teachers resulted in the selection of three important features of a classroom environment that would enable this kind of safe argumentation: students are accepting of wrong answers, misconceptions are an opportunity to learn together, and students share their thinking and question the thinking of others.

The design of the PD for this study was also based on the guidance provided by Thompson and Zeuli (1999) for creating a transformative learning experience for teachers. To create cognitive dissonance, several problem were provided for teachers to engage in reasoning and sharing of their thinking with others that would bring up questions and uncertainty that would need to be resolved through inquiry and discussion, and to provide sufficient time for that process to occur. Through these experiences teachers were challenged to support their own claims about their understanding of integers which deepened their understanding and enabled them to experience the value of argumentation. An engaging discussion broke out when two groups were arguing over the claim that the number line was acceptable for addition, but it was not a good model for subtraction. The discussion that followed lasted almost an hour as teachers struggled with the meaning of representing subtraction on a number line, whether their method would work all the time or just sometimes, and the challenges they felt students would have with the model. In the end the teachers agreed that the number line model might make more sense to students then other models used previously, such as the cancellation model with colored chips.

For the purpose of this study, the curriculum for the integers unit of the program was revised based on a review of research literature on improving student understanding of integer operations to include more activities exploring integers with a number line. During the development of the unit, feedback was provided on improvements that could be made by university professors, graduate students, teachers in the district (including those who previously taught in the program), and the district Secondary Mathematics Supervisor. The goal was for this revised unit to develop the concept of operations on positive and negative numbers in a way that connects the concepts to a real world experience and a number line representation that is comprehensive in its application to all operations of integers. The number line revised unit for integers incorporated the use of vectors on a number line that integrated an application called NUMLIN on the TI-73 calculator with publicly available lessons called "Walking the Line" from the Texas Instruments education technology portal. Figure 1 provides an example of how multiplication of integers was explored with the calculator in these activities, where multiplication is represented as repeated addition or subtraction.

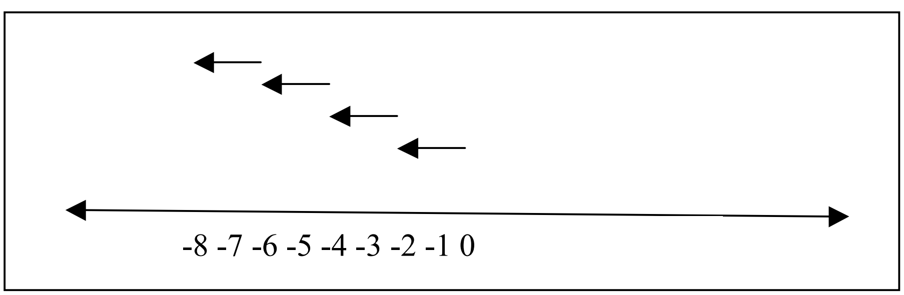

Figure 1. Number line Model for Multiplication of 4 x -2

The students used these number line explorations to discover the way operations on integers work by manipulating the vectors on the TI-73 calculator number line. The curriculum for the summer program also included activities from the *Navigator: Positive and Negative Numbers* curriculum module (America's Choice, 2008), which was developed to address student misconceptions and includes the vector number line representation. Daily journal activities were written for students to practice responding to misconceptions of other fictitious students

Data Collected

Teacher demographic data was collected with a short survey given to teachers during the PD. To measure teacher PCK, an assessment was designed based on three sources: a pre-service teacher's guide entitled *Fostering Children's Mathematical Power: An Investigative Approach to K-8 Mathematics Instruction* (Baroody & Coslick, 1998), research by Turnuklu and Yesildere (2007) with pre-service teachers in Turkey about their mathematical understanding of integer operations, and data collected in a pilot study from interviews of students in grades 7, 9 and 11 (Varma, Harris, Schwartz, & Martin, 2008). To measure student achievement the pretest and posttest from the America's Choice (2008) *Positive and Negative Numbers* curriculum were used, since they had been used for the two previous years, so that the student results of the 2010 summer program could be compared to the results of the 2009 summer program.

Data Analyses

The teacher PCK assessments were scored based on a rubric created from a review of the responses of a volunteer sample of 13 people (teachers and graduate students). The student assessment was scored according to the curriculum guidelines in the teachers' guide. A Hierarchical Linear Model (HLM) was used to examine the relationship between teacher content and pedagogical knowledge of integers and mathematics learning related to the fourth research question. A two-level Hierarchical Linear Model with student math scores as the level one outcome variable (a within-class model) and individual class variables, such as mean math score, as the level two outcome variables (a between-class model) was used to determine the variance in student test scores from pretest to posttest as a function of their class assignment. Classroom-level predictors (teacher content and pedagogical knowledge of integers and years of teaching experience) were added into the level two models to determine whether they explained the variance in mean class scores and pretest/posttest performance slopes. Because the relationships between variables measuring student learning are at least partially dependent on the larger context (the classroom) in which learning occurs, teacher PCK should partially explain the variance across classes, as should the years of teaching experience of a teacher. It was of interest to see whether PCK following PD would outweigh experience in explaining the variance across classes. In addition, an independent samples t-test was used to compare the performance of students in the 2010 program to the previous year's students.

Results

When the pretest and posttest responses of the 18 teachers were compared the change from pretest to posttest in teachers' PCK was positive and statistically significant ($t = 3.29$, $p < .01$). There was also a statistically significant increase ($t = 2.37$, $p < .05$) in teachers' ability to explain the sign of the answer to the problem -5 x (-8) as shown in table 1. Teachers also made statistically significant improvement ($t = 2.55$, $p < .05$) in providing real world and domain examples of applications for integers.

Question (N = 18 teachers)	Pretest Mean (*SD*)	Posttest Mean (*SD*)	Difference (SE)	*t*	*p*-value
Q1. 5 – (-8)	.67 (.77)	1.11 (.96)	.44 (.32)	1.41	.18
Q2. -5 x (-8)	.39 (.70)	1.00 (.97)	.61 (.26)	2.37	.03*
Q3. (-6) + (+7), 6 – (+7)	1.28	1.83	.56	3.34	$p < .01$

	(.83)	(.38)	(.17)		
Q4. 4 – 7 = 3	1.44 (.62)	1.61 (.61)	.17 (.12)	1.37	.19
Q5. 3 – 5, 3 + (-5)	.50 (.71)	.89 (.68)	.39 (.20)	1.94	.07
Q6. Prior Argumentation	1.06 (.87)	1.22 (.88)	.17 (.20)	.83	.42
Q7. Applications	1.06 (.54)	1.33 (.59)	.28 (.11)	2.55	.02*

Note. (a) These values represent the average raw score out of 2 points earned by teachers on the pretest and the posttest for each question. Teachers could earn 0, 1, or 2 points per question. The total questions were worth 14 points. (b) *Statistically significant difference at the $p < .05$ level.

Table 1. Improvement in Teacher PCK Following PD

When the pretest and posttest performance of students in the 2010 program was compared to the performance of students in the 2009 program there was statistically significantly difference between the improvements made for the students in the 2010 program compared to the 2009 program as shown in table 2.

Percent Correct out of 100	2010 Mean (n=177) (*SD*)	2009 Mean (n = 177) (*SD*)	Difference (SE)	*t*	*p*-value
Pre-test	37 (17)	43 (19)	-7 (4)	-1.77	.08
Posttest	51 (15)	49 (21)	2 (4)	.41	.68
Improvement	14 (17)	06 (19)	8 (3)	2.20	.03*

Table 2. Comparison of Student Knowledge of Integers 2010 vs. 2009

The HLM conditional model was as follows:

Level-1 Model

$$Y_{ij} = \beta_0 + \beta_1\text{*(Pretest)} + r_{ij}$$

Level-2 Model

$$\beta_0 = \gamma_{00} + \gamma_{01}\text{*(Teacher Experience)} + \gamma_{02}\text{*(Teacher PCK Pretest)} + \gamma_{03}\text{*(Teacher PCK Posttest)} + u_{0j}$$

$$\beta_1 = \gamma_{10}$$

The findings for this conditional model are summarized in table 3. The findings reveal that, after controlling for prior student and teacher knowledge as well as teacher experience, teacher's PCK significantly predicted student posttest performance (t (14) = 2.37, p = .033). Thus, as teacher's post-intervention PCK increased by one point, there was a 0.22 increase in student math posttest performance. When comparing the conditional model to the unconditional model, the addition of the teacher experience, teacher pretest knowledge and teacher posttest knowledge covariates explained 27 percent of the variance after adjusting for differences in student pretest. This positive relationship between teacher posttest PCK and posttest student math achievement suggests that when teachers have the necessary PCK related to integers and integer operations, students' overall learning of integer concepts and procedures for solving integer operation problems improve.

Parameter	Unconditional Model				Conditional Model			
	Estimate	*SE*	*t*	*p*	Estimate	*SE*	*t*	*p*
Fixed effects								
Intercept	50.79	1.73	29.28	.000	50.49	1.59	31.70	.001

Level 1 variance	135.02	—	—	—	135.31	—	—	—

Table 3. Comparison of Results of Conditional vs. Unconditional HLM Analysis

Discussion

The observations made during the PD were that most of the teachers were engaged in the activities where they experienced argumentation around representations of addition and subtraction of integers. There was evidence during the stations activities, that teachers were already making connections as to how they could use certain activities and certain questions to form the problem that would be the center of the argumentation for the students. On the teacher PCK posttest, several teachers shared experiences with students resisting participation in discussions due to low confidence in mathematics and a concern about being wrong. Others shared the challenges of facilitating small group discussions when one of the students was overly confident and verbal, causing the other students just to listen and not share their ideas for fear of being wrong. Twenty-four percent of the teachers admitted to not engaging students in argumentation. Close to 50 percent of teachers on the posttest continued to believe that the only way to understand why -5 x -8 was positive was because of a rule that when one multiplies two negatives (or an even number of negatives) one gets a positive, despite their exposure to other representations and strategies during professional development and through the curriculum they implemented with students.

In conclusion, the professional development and curriculum modifications resulted in statistically significantly positive gains in teacher PCK and student achievement. The change in the professional development, compared to the previous year resulted in less of a focus on student activities and more on developing teacher PCK. As a result, teachers who were originally unable to explain why multiplying two negative numbers results in a positive number were now able to explain their reasoning conceptually on the posttest. Other teachers who did not differentiate between an operation of subtraction and the negative sign of a number at pretesting made improvements in understanding the distinct roles of each of these components of a mathematical expression. The resulting positive change in teacher PCK was associated with positive gains in student understanding on the posttest. To have such a positive effect on teachers and students in just six hours of PD and three weeks of a curriculum and instruction intervention is encouraging for future PD development.

STOCHASTICS KNOWLEDGE OF PRESERVICE TEACHERS

Angie Conn
Virginia Tech
aconn@vt.edu

This research examined preservice teachers' knowledge of probability and statistics. Clinical interviews were conducted with 2 preservice teachers in which they solved stochastics problems dealing with perceptions of randomness and strategies for a probabilistic game. Results highlight strengths and weaknesses of their stochastics understanding, as well as their perceptions of probability and statistics education in secondary schools. The implications for teacher education are discussed.

Purpose

Statistics and probability (stochastics) topics have been included as essential ideas in both National Council of Teachers of Mathematics (NCTM) standards documents (1989, 2000). However, there is a concern that mathematics teachers do not have the necessary background knowledge for teaching stochastics (Jones, Langrall, & Mooney, 2007; Shaughnessy, 2007; Stohl, 2005). This lack of knowledge is not surprising considering many elementary and secondary teachers have had few or no university courses or professional development dealing with stochastics (Stohl, 2005; Watson, 2001).

As noted in Jones et al. (2007), there is limited research on the stochastics knowledge of pre- and in-service teachers. This study aims to add to the body of research by examining the stochastics knowledge of two preservice teachers (PSTs). The purpose of my research is to discover what they know about probability and statistics and how that knowledge will affect their future teaching.

Literature Review

In this review of the literature, I will focus on several studies that examine preservice (or in-service) teachers' knowledge of stochastics and how teacher education programs prepare future teachers of probability and statistics. Specifically, I will highlight research concerning teachers' stochastic understandings and misconceptions.

Although there is little research on stochastics in teacher education, some studies have found areas of strength and weakness in PST knowledge (Batanero, Godino, & Roa, 2004; Baturo, Cooper, Doyle, & Grant, 2007; Canada, 2006; Koirala, 2003) and the knowledge of in-service teachers (Liu & Thompson, 2004; Watson, 2001).

In Canada's (2006) study of thirty elementary PSTs' notions of variability, subjects were enrolled in a mathematics content course in which they performed various stochastic activities. Canada found the participants had a good understanding of the difference between theoretical results and experimental results. However, a negative aspect of this understanding led participants to believe that if theoretical predictions did not match actual results, then all results are possible and equally likely. When Canada asked subjects to evaluate statistical graphs, most subjects referenced the idea of average. Some focused only on average, while many also looked at the other three components of distributional reasoning (Canada, 2006): range, shape, and spread. This study also commented on the link between proportional reasoning and probabilistic thinking. "An over-reliance on proportional reasoning can lead to a restricted expectation of variation, but an under-reliance on proportional reasoning can also lead to poor expectations" (p. 42).

Koirala (2003) focused on secondary PSTs' use of formal and informal reasoning when solving probabilistic problems in both individual and paired settings. On the individual task, PSTs used both formal (learned from university courses) and informal (based on intuitions and experiences) probabilistic reasoning. When in pairs, the PSTs wanted to use formal reasoning. When a formal thinker (from the individual task) was paired with an informal thinker, the formal thinker began the conversation and the informal thinkers agreed with their partners' solutions. In final individual interviews, all eight subjects initially offered formal reasoning. However, one informal thinker changed her mind and reverted to her informal (incorrect) answer in which she used a representative heuristic. In a similar but more difficult problem, only three of the PSTs used formal reasoning. The author attributed these inconsistencies to "conflict between their informal beliefs and their mathematical knowledge of probability" (Koirala, 2003, p. 153). Even students with a thorough math background did not have a complete understanding of probability. Many were likely to solve a problem incorrectly despite having the requisite formal reasoning required to solve the problem.

Koirala's (2003) results show the differences in reasoning when students are working alone or with a partner. However, she seems to imply that formal reasoning always led to correct solutions, while informal reasoning did not. It was not clear why Koirala seemed to think formal reasoning was always the preferred solution method.

In Liu and Thompson's (2004) work with eight high school teachers, they found their subjects held many viewpoints on probability, including using subjective judgment, not knowing a solution because the predicted event has not actually occurred, and a formal stochastic viewpoint. Positive findings included that teachers understood how variability decreases as sample size increases. Negative results showed that the teachers were not familiar with hypothesis testing, even though some of the teachers were required to teach that topic.

The study (Liu & Thompson, 2004) also found that some teachers thought that a probabilistic situation could have multiple interpretations, while others did not. Both groups, though, wanted to find the "correct answer". In trying to find those answers, the teachers trusted solutions by those they viewed as experts, but they were not confident in their own reasoning. Despite the discussions on formal probability theory, the teachers thought a correct answer could always be determined using a computer simulation. The teachers' reliance on computer models is interesting, because the teachers stated they believed students learned about probability by simply hearing the concepts explained correctly. "This way of teaching was also projected by the ways in which teachers negotiate meanings. We found that teachers often dismissed the opposing point of view as "mistakes", convincing others that they are wrong by telling them they are wrong, instead of trying to understand the other person's intention" (Liu & Thompson, 2004, p. 6).

Through the implementation of a self-designed survey, Watson (2001) sought to understand teachers' strengths, weaknesses, and opinions on the teaching of stochastic topics. Her subjects were 28 secondary and 15 primary level teachers in Australia.

When asked to identify important factors for teaching chance & data, teachers' responses were grouped into four themes: teacher, student, content, and school issues. Twelve teachers listed similar topics as being the most enjoyable for their students and their selves: graphing, normal distribution, surveys and data collection, analyzing and interpreting data, and various topics in probability. Many teachers said their students enjoyed hands-on activities such as probability games.

Teachers rated nine topics by their confidence in teaching each topic, 'odds' had the lowest mean, 'graphical representation' had the highest. All mean confidence ratings by secondary teachers were higher than the highest mean by primary teachers except 'odds'. Secondary teachers were significantly more confident about six topics: equally likely outcomes, average, basic probability calculations, median, graphical representation, and sampling. The difference in confidence levels was attributed to stronger mathematical backgrounds of the secondary teachers.

In one section of the survey, Watson (2001) asked participants to read stochastic problems, anticipate different ways students might respond, and explain how they might use this problem in teaching their classes. The author compared teacher responses with actual student responses to these same questions. In a problem dealing with odds, teachers successfully anticipated student answers.

Baturo et al.'s (2007) study highlighted some misconceptions held by elementary PSTs. The subjects were given a task in which they had to determine if a spinner was fair and confirm their answer by using three testing methods. After examining the spinner, only 41.9% of the participants correctly thought the spinner was fair. After using the first testing method (an overlay that divided the circle into 6 equal parts), many maintained the spinner was unfair, even though they could see that each color had an equal area. After performing & recording trials using the spinner, many teachers were still not convinced of the spinner's fairness. Baturo et al. attribute this to the PSTs' deterministic view of mathematics that would not validate a result that did not show exactly a third of the trials resulting in each color.

Methods

My initial goal for this study was to conduct a teaching experiment in which I would observe PSTs as they worked through a series of stochastics problems. I wanted to recreate Batanero et al.'s (2004) study, and compare their results with mine. Due to time limitations, my research was not a full-scale teaching experiment, but rather consisted of two separate clinical interviews in which I simulated the two learning experiences described by Batanero et al. (2004).

Batanero et al.'s study focused on preservice primary and secondary teachers enrolled in a mathematics methods course. All PSTs were statistics majors in their fourth or fifth years of study at the University of Granada in Spain. Throughout the course, the PSTs engaged in learning activities designed to engage them in learning and discussion of probability and statistics topics. The two activities presented in the study (Batanero et al., 2004) dealt with perceptions of randomness and developing a winning strategy in a probabilistic game. These experiences highlighted the PSTs understandings and misconceptions concerning stochastics topics.

The participants in my study were two PSTs enrolled in a master's of education program at a large southeastern university in the United States. Both students, Anna and Eric, majored in mathematics and took Statistics for Engineering as undergraduates. Neither PST had taken a teacher preparation course focused on probability and statistics.

Results

In this section, I will describe the learning activities and results from my clinical interviews, as well as report the findings from Batanero et al.'s (2004) research. The first task (Figure 1) concerns perceptions of randomness.

Perceptions of Randomness

Some children were each told to toss a coin 40 times. Some did it properly. Others just made it up. They put H for Heads and T for tails. These are Daniel and Diana's results:

Daniel: H T H T T H H T H T H H T T H T T H H T T H T H H T T H T H T H T H T H T T H T

Diana: H T T T H T T H T H T T T H T T T T H H T T T H T T H T T H T T T T T H T T T H T

Did either or both Daniel or Diana make it up? How can you tell?

Figure 1. Perception of randomness task. Batanero et al. took this task from Green (1991).

I told the PST this task had been used with secondary students to understand their ideas about randomness. The PST then gave their thoughts on this task. Both PSTs began by comparing the number of heads and tails in each sequence. They saw both patterns as possible, but each said that Daniel's was more probable because the outcome was closer to the expected number of heads and tails for forty coin tosses. In order to learn more about Eric and Anna's understandings, I asked them for their thoughts on the patterns of the sequences. Even with leading questions, they confused the probability of a certain sequence of heads and tails with the total outcomes of heads and tails. This finding is similar to Batanero et al. (2004); they also found that students recognized frequency properties more easily than run properties.

Next, I presented the PST with data from secondary students' work with the initial task as shown in Table 1. The results show that more students considered Daniel's sequence to be random, as well as differences between the 14- and 18-year-olds' responses. When asked to explain the students' thinking, Anna said that more students think Diana is cheating because they believed it was unlikely for her to obtain four tails in a row. This is the first mention of the pattern of the outcomes as opposed to the count of heads and tails. Anna did not see a noticeable difference between the younger and older students. Eric studied the table quietly for a few moments, and then noticed that a higher proportion of older students responded, "I don't know." He explained that more 18-year-olds might understand there is no way to actually tell whether Daniel or Diana cheated, because each sequence is a possible outcome. He went on to discuss how some students, possibly the 14-year-olds, would have a more rigid belief that when flipping coins, heads should occur close to (or exactly) half of the time. This idea is mentioned in the original study (Batanero et al., 2004), "Whilst a student can think he/she has 'proven' that a sequence is random, the statistician would just say that there is no reason for rejecting the sequence randomness" (Section 4.3, last para.). Batanero et al. (2004) did not report specific PST responses to the table, but they described how changes in the sequences or wording of the task might lead to different student results.

	14 year-old (n=147)		18 year-old (n=130)	
Response	Daniel	Diana	Daniel	Diana
He/she made it up	54 (37%)	83 (56%)	30 (23%)	63 (49%)
He/she did it correctly	86 (58%)	53 (36%)	82 (63%)	48 (37%)
I don't know	7 (5%)	11 (8%)	18 (14%)	19 (14%)

Note. This table shows the responses to the previous question obtained by Serrano (1996) from 277 secondary school students.

Table 1. Frequencies and percentages of secondary school students' answers.

The final discussion of the task occurred after I showed examples of student reasoning (Figure 2) to the PST. Both Anna and Eric explained what a student might be thinking if they gave each of the three responses. I then asked them to put themselves in the role of a teacher, and to consider what they would do with students to continue to explore the idea of randomness. Both of the PSTs suggested letting student perform the coin flipping activity in class. Anna would have her students compile their results and compare the aggregate data with the original data. This would help students see the likelihood of obtaining Daniel or Diana's results. Eric's reasoning behind performing additional trials was to show students that it is possible to obtain many heads or tails in a row. He was concerned that students would not believe that a long sequence of heads was possible unless they saw it happen. During this discussion, Eric brought up the idea of the gambler's fallacy, and mentioned that he would observe the students to see if they held that misconception.

Batanero et al.'s (2004) results focus mainly on how secondary students interacted with this problem. They explain how students consider irregular patterns and even distributions as indicators of randomness. Students considered Diana's outcome as too different from the expected outcome, so they labeled her as the cheater. For students who analyzed the runs, they either thought Diana's was too irregular to be random, or Daniel's was too regular to be random.

Some reasons given by students in Serrano's (1996) research to justify that Daniel or Diana were cheating were the following:

- The sequence pattern is too regular to be random, results almost alternate;
- The frequencies of heads and tails are too different;
- There are too long runs; heads and tails should alternate more frequently.

Figure 2. Explanations of randomness task responses.

Strategy for a Probabilistic Game

The second activity began with the description of a game shown in Figure 3.

We take three counters of the same shape and size. One is blue on both sides, the second is red on both sides and the third is blue on one side and red on the other.

We put the three counters into a box, and shake the box, before selecting a counter at random.

After selecting the counter, we show one of the sides. The aim of the game is to guess the color of the hidden side. We repeat the process, putting the counter again in the box after each new extraction. We make predictions about the hidden side color and win a point each time our prediction is right.

Figure 3. Description of probability game.

After making sure the PST understood the game, I explained how we would be using Fathom statistical software (Finzer & Swenson, 2001) to create a simulation of the game. Each game would consist of ten trials, so I gave the PST a sheet of paper to record their responses and outcomes (Figure 4). The purpose of the activity was to devise a winning strategy for the game.

Trial	1	2	3	4	5	6	7	8	9	10
Seen color										
Predicted color										
Hidden color										

Figure 4. Game score sheet.

Anna discovered the correct winning strategy immediately. She realized that if she predicted the same color as the seen color, then she would have a two-thirds chance of winning each trial. Before we played the game a second time, I asked her how many trials she expected to win. She said she would win about five or six of the ten trials. I asked her to elaborate, because she earlier she had mentioned a two-thirds probability. Anna explained that theoretically, she would win 66.6% of the time using her strategy. Since someone cannot win exactly two-thirds of ten games, she expected to win around six or seven games in each round. Anna pointed out that even with using the strategy, there could be a variety of outcomes, but on average, she expected to win two-thirds of the time.

It took Eric a few rounds to realize the winning strategy of the game. He was focused on the total reds and blues in the bag. Since there were three red sides and three blue sides, he correctly identified the probability of the counter being either color was one-half. I asked guiding questions to lead him to the correct strategy. Upon further review of the interview recording, I believe that I did not explain the game well and Eric did not realize I wanted him to develop a strategy. His thinking was at first centered on the final outcome of the counter, without regarding the ‘seen’ side. After Eric discovered the winning strategy, he was able to prove why the strategy worked. He used a tree diagram to help him understand the probability and justify his reasoning.

Batanero et al. (2004) found that less than half of the PSTs chose the correct strategy at beginning of game. They were given class time to discuss their strategies and try to convince each other of their reasoning. Even after most of the teachers came to the solution, not all could provide mathematical justification for why the strategy worked. This was surprising to the researchers because of the simplicity of the problem and the strong statistics training of the PSTs.

Finally, I showed Eric and Anna some of the strategies used by the PSTs in Batanero et al.'s study (2004) which are displayed in Figure 5. The PSTs gave examples of student conceptions that would lead them to each of the strategies. They also gave suggestions on how they might lead the student to discover the correct strategy. Using this problem with a group of students, both PSTs suggested playing the game multiple times and aggregating the win and loss data for various strategies employed by students.

Common strategies in this game are:
A: Predicting red and blue alternatively;
B: Choosing red (blue) in all the trials
C: Predicting the color at random;
D: Two blues, one red (or something similar)
E: Predicting the color shown on the visible side
F: Predicting the color contrary to that shown on the visible side.

Figure 5. Possible strategies for the game.

Conclusions

Although my study only considered two PSTs, I present some information that leads us to a better understanding of the stochastic knowledge of PSTs. Both PSTs in the study see the importance of teaching probability and statistics. Eric feels comfortable with teaching it, while Anna does not; however, both PSTs have strong content knowledge that will help them in the classroom. Even more encouraging is the way that each PST engaged with the mathematics. They seem confident that they can reason through a stochastics problem to find the solution, even if they do not initially have a strategy. I was also pleased that both PSTs stressed the importance of experimentation when learning probability and statistics. The idea of teaching rules or formulas was not suggested in either PST conversation.

Another outcome I noticed is that neither PST used much probability and statistics vocabulary to describe their thoughts. For example, although both PSTs discussed the idea of variability, neither one used the term. In addition, Anna and Eric were both not familiar with the term 'sample space'. They both seem to have a strong stochastics understanding, but I would not be surprised if they did not score high on a probability test, given their unfamiliarity with the vocabulary. The difference between test scores and actual problem solving ability might be an interesting area for further research.

Another possible topic for further study is to summarize the stochastics experience of mathematics teachers during their undergraduate, graduate, or in-service trainings. I would like to see if certain mathematics education courses made teachers more comfortable and competent at teaching probability and statistics topics.

In conclusion, the results of my study show promise for the future of stochastics education. More work must be done to ensure that all teachers are prepared to teach this important part of the mathematics curriculum.

MIDDLE SCHOOL STUDENTS' GROWTH IN UNDERSTANDING OF PROBABILISTIC INFERENCE

Marggie D. González

Hollylynne S. Lee
North Carolina State University
hollylynne@ncsu.edu

Reasoning informally about statistical inference is being able to make inferences about data without using any formal statistical method or procedure. In this paper we aim to share a probabilistic inference framework we developed to describe how students' informal probabilistic inference changes while being exposed to instruction. The study investigated changes in six middle school students' reasoning before, during, and after a 12-day instructional sequence using a probability simulation software tool. Findings indicate that students are more aware of the effect of sample size when drawing conclusions and making probabilistic inference at the end of the instructional program.

Introduction

Interpreting data and being able to use it to make predictions and decisions are essential tools in order to be informed, educated, and competent citizens in our modern society. Individuals must have the ability to critique, interpret, evaluate, and express their own opinion about the information they receive (Shaughnessy, 2007). Being able to evaluate evidence (data) and claims based on data is an important skill all students should learn as part of their educational programs since they will need to informally infer conclusions from data presented through different representations (e.g., tables, graphs) by the media in their everyday lives. According to Shaughnessy (2007) research has started to pay attention to students' understanding of statistics and students' statistical thinking. Building informal notions of inference within statistical and probabilistic contexts has been advocated for over the past decade within the U.S. (NCTM, 2000; CCSSO, 2010).

Theoretical Foundations

Many authors have described informal statistical inference in different ways. Rubin, Hammerman, and Konold (2006) described it as a reasoning that involves consideration of properties of aggregate including signal and noise and types of variability, the effect of sample size on the accuracy of population estimates, and controlling for bias in order to get a sample that is representative of the population. Zieffler, Garfield, delMas, and Reading (2008) defined it as the way students use argumentation and data-based evidence to support the connections they build between observed sample data and the unknown population. Pfannkuch (2005) stated that statistical inference is concerned with drawing conclusions about specific characteristics of a particular population based on evidence obtained by a sample. The authors have defined informal statistical inference as making generalizations beyond the data, using proper language, argumentation, and data-based evidence to support their findings. The inference is informal in the sense students have not had any formal instruction of methods of statistical inference.

A wide selection of studies have been conducted in order to study students' informal statistical inference (Ben-Zvi, 2006; Rubin et al., 2006; Shaughnessy, 2007). Research has found that even young children can collect data, display it in an adequate way, and make inferences about the underlying population based on the data collected. Most of these studies have had students using dynamic statistical software to analyze data and make informal statistical inference about a specific characteristic of a population based on a collected sample. For example, in Ben-Zvi's (2006) study, students were asked to make generalizations about height and arm span using data students collected through a questionnaire among peers.

Probabilistic inference is also based on data collected and the main objective is to predict the underlying probability distributions, obtained theoretical or empirically through experimentation or simulations. Probabilistic inference has been widely used with students in contexts where a theoretical probability distribution can be easily estimated (i.e., coins, dice, and spinners) (Jones, Langrall, Thornton, & Mogill, 1997); but how do students reason about situations where a theoretical probability distribution is not easily estimated? According to NCTM (2000), "through the grades, students should be able to move from situation for which the probability of an event can readily be determined to situation in which sampling and simulations help them quantify the likelihood of an uncertain event" (p. 51). Probabilistic inference can be use as a preamble to informal statistical inference, starting with contexts in which the theoretical probability is known, and then moving to situations in which a theoretical probability is unknown where sampling and simulations can be used to quantify the likelihood of an uncertain event.

From a wide selection of research on students' statistical informal inference a narrow selection have examined the growth of students' probabilistic reasoning while being exposed to instruction (Jones et al., 1997; Shaughnessy, 2007; Stohl & Tarr, 2002), and only a few have used technology as a tool for students to carry out simulations (e.g., Lee, Angotti, & Tarr, 2010; Pratt, Johnston, Ainley, & Mason, 2008; Stohl & Tarr, 2002). Various technology tools have been used with positive results to study students' probabilistic reasoning. Of importance to our work, the results of these studies have shown that using simulation tools help students develop a better understanding of empirical probability, particularly the importance of sample size in being able to make generalization beyond data.

This study intends to bring some insights on how students develop important concepts in probabilistic inference, and how they may be influenced by instruction. In particular, we seek to answer the question: *How do middle school students' ability to make probabilistic inferences change over the course of instruction?*

Methods

The data in this study was part of a larger study that took place in a public middle school in the southern United States. A 12-day instructional program engaged an average-level 6th grade mathematics class (n=23) in a probability unit using *Probability Explorer* (Stohl, 1999-2002) as a simulation tool during the first month of classes (see Stohl & Tarr, 2002, for details on the instructional design). Prior to instruction, six students were carefully selected to be used as case studies. The selection was based on students' scores from two tests: a standardized mathematics achievement test, and a pretest on probability concepts. The students were chosen by their relatively consistent ranking on both tests (high, middle, low). The six students included four boys (two Caucasians, one Hispanic, and one African-American) and two Caucasian girls. Six sources of data collected in the larger study were used for the current focused study: a pre-interview and a post-interview of six case study students, students' worksheets, a pre-test, post-test, and a retention test. The pre-test was used to obtain evidence about students' knowledge of probability and students' informal statistical inference before instruction. After the pre-test, but before instruction started, semi-structured interviews were conducted with six case study students. During instruction, students worked in pairs and completed a series of tasks and recorded their work on handouts. Immediately after the instructional sequence, a post-test was given that was parallel in construction to the pre-test. Within a week after the last day of instruction, a post-interview was conducted with the six case study students. Ten weeks later a retention-test was administered. After examining all sources of data,13 tasks, some from each data source, were selected to be used to more closely analyze for evidence of students' probabilistic inference (see Table 1). Tasks were selected based on whether or not students were explicitly asked to make inferences and whether or not responses from all six students were gathered.

Task and Sources	**Context**	**Concepts/Constructs**
Task1PreT *Task2PreT* (Pre-Test)	Fairness of an old buffalo nickel found on the street.	• Importance of sample size. • Variability within and across samples. • Propose data collection (sample size larger than 50) and how data would be analyze (looking at the distribution).
Task3PreI (Pre-Interview)	A bag of marbles	• Given the total number in the bag, predict its content. • Importance of sample size.
Task4PreI (Pre-Interview)	Estimate the likelihood a plastic cup would land upside down.	• Estimate proportion of unknown population. • Importance of sample size in order to make generalizations beyond the data collected.
Task5Inst (Instruction)	Bag of Marbles with known total, but unknown content	• Given the total number in the bag, predict its content using PE • Importance of sample size.
Task6Inst (Instruction)	Fish in Lake with 2 types of fish, but unknown total	• Estimate proportion of unknown population. • Importance of sample size.
Task7Inst (Instruction)	Decide whether or not the dice produced by certain companies were fair or not	• Estimate proportion of unknown population • Importance of sample size. • Variability within and across samples
Task8PostT *Task9PostT* (Post-Test)	Bottle cap found in the sidewalk. Is it fair?	• Importance of sample size. • Variability within and across samples. • Propose data collection (sample size larger than 50) and how data would be analyze (looking at the distribution).
Task10PostI (Post-Interview)	Two flavors in the jar. Proportion of each flavor?	• Given the total number in the bag, predict its content using PE • Importance of sample size.
Task11PostI (Post-Interview)	Estimate likelihood toothpaste cap would land upside down	• Estimate proportion of unknown population. • Importance of sample size.
Task12RetT *Task13RetT* (Retention Test)	Fairness of unusually shaped button	• Importance of sample size. • Variability within and across samples. • Propose data collection (sample size larger than 50) and how data would be analyze (looking at the distribution).

Table 1. Tasks and items selected from the sources of data

Development of a Probabilistic Inference Framework

In order to characterize the complexity of students' ability to make informal statistical inference within a probabilistic context, it was necessary to develop a coherent framework. Although several frameworks were found in the literature (Jones et al., 1997; Makar & Rubin, 2009) there was not a framework to study students' inferential reasoning in a probabilistic context. Similar to the frameworks developed by others, we based our framework on the SOLO

Taxonomy (Biggs & Collis, 1982). The SOLO (Structure of the Learned Outcomes) Taxonomy postulates that all learning occur in five modes of functioning: *sensorimotor*, *ikonic*, *concrete symbolic*, *formal*, and *post-formal*. The growth within each mode is characterized through a learning cycle. The sequence of levels refers to a hierarchical increase in the structural complexity of the responses in a particular mode and can be used to classify the outcomes of learning within any given mode. The five levels of response within each mode are: (1) *pre-structural* – the learner is frequently distracted or mislead by irrelevant aspects of the situation; (2) *uni-structural* – the learner focuses on the problem, but uses only one piece of relevant information; (3) *multi-structural* – the learner uses two or more pieces of data without perceiving any relationship between them; and (4) *relational* – the learner can now use all data available, integrating each piece of information.

Comparing the literature on students' informal statistical inference there are similarities and differences in the key principles researchers believe are important when investigating how students reason about informal statistical inference. We identified three constructs as important key principles to be included in the framework: *generalization, variability, and investigation* (see Gonzalez, 2010, for details about the development of the framework). Once an initial draft of the framework was developed based on the research literature, successive refinements were made through sampling students' work on a task and considering how well the categories characterized their work. A sample of tasks was separately coded by both authors and when disagreement existed, the authors discussed the coding in order to reach agreement. Several back and forth coding and refinements were made to result in the final framework shown in Table 2. For each construct, a brief description is included for what was expected for each of the four levels.

	Pre-structural	**Uni-structural**	**Multi-structural**	**Relational**
Generalization (G)	• Makes generalizations based on their previous experiences and their intuitions. Ignores sample size.	• Makes generalizations based on a single part of the information given ignoring the others.	• Makes generalizations based on most of the given information or data collected but still ignoring others.	• Make generalizations based on all the information given or the data collected. Recognizes the importance of large samples to make generalizations.
Variability (V)	• Attributes variability to luck or chance in all contexts. No recognition that variability can be described/controlled.	• Recognizes variability among individual results within a single sample (e.g., I got more 5's than 3's). • Has low expectation of variability from an expected distribution based on some theoretical probability distribution.	• Recognizes variability among individual results within a single sample and recognizes variability across different samples (e.g., last time I got more 5's, this time I got more 1's). • Has a better sense of expecting some variability from theoretical probability distributions, but may expect too much variability.	• Recognizes variability within and across samples and relates variability to characteristics of the underlying probability distribution.

Investigation (I)	• Does not propose a data collection process • Believes sampling does not tell you anything about the underlying population.	• Proposes a data collection process, either appropriate or inappropriate (e.g., uses a small sample size), and does not describe how to assess the results.	• Proposes an appropriate or inappropriate data collection process and describes how the results could be analyzed, although not using the most appropriate approach.	• Proposes an appropriate data collection process (e.g., a large sample size) and describes how the results will be analyzed (e.g., from the distribution of the outcomes)

Table 2. The Probabilistic Inference Framework

Once a final coding framework was developed, each of the 13 tasks for each of the six students was coded by the first author. A sample of 2-3 tasks for each student was selected for the second author to code in order to provide reliability checks. At this point in the coding, it was rare for there to be disagreements between coders. When a few disagreements arose, the researchers discussed reasoning behind the codes until a final agreed-upon code was reached.

For the purpose of this paper, we are focusing on students' informal probabilistic inference within the generalization construct. Generalization builds upon the ability students have to move from looking at individual cases to look at the data as an aggregate and beyond. Generalization is making a claim about the aggregate that goes beyond the data (Makar & Rubin, 2009). Statistical generalizations are abstractions from particular cases (sample) that are applied to a broader set of cases (population). Generalizations should not be based on intuitions or previous experience; it has to have data as evidence. This evidence should provide information about the plausibility of students' claims or predictions. Students could provide graphs, tables, or any other representation they believe would help them support the generalizations they are making. In making generalizations beyond the data students should take into account the size of the samples they are using to draw their conclusion. At higher levels, it is expected that they change their perceptions about the role sample size plays when making inferences as well as how to use the information obtained through the simulations to draw their conclusions and generalizations.

Results

The generalization construct was used to observe the way students were making generalizations beyond a data collected. Some students used their intuitions and ignored the fact that sampling could provide a good estimation about the underlying population distribution. Others reasoned and made generalizations based on small samples using the "total weigh approach" strategy (Lee, 2005). And others, although not reasoning appropriately about how to use the result to make generalizations about the underlying population, did propose a large sample size. Table 3 illustrates the assigned levels used to characterize each student's responses. The levels are represented with the letters P (pre-structural), U (uni-structural), M (multi-structural), and R (relational). All names are pseudonyms; Lara and Dannie composed the high-scoring group, Manuel and Brandon the average-scoring group, and Greg and Jasyn the low-scoring group.

During all the *pre* tasks (Task1PreT through Task4PreI) Lara reasoned at a pre-structural level, she was not paying attention to sample size and was not using the distribution of the outcomes to make generalizations. For example on Task1PreT, when given data that a coin was tossed 1000 times resulting in 643 tails and 357 heads and asked if the coin was fair, she concluded a coin "can always be a fair coin unless it always lands on one side." This represents a pre-structural level response because she ignores the large sample size and seems to base her reasoning on an intuition that if both sides of the coin occur it is a fair coin. During instruction (Task5Inst through Task7Inst) her reasoning increased to a multi-structural level, as she demonstrated attention to sample size and using the distribution of outcomes to make generalizations, although not in the most appropriate way. She continued on a constant level of reasoning toward the end of the unit.

A similar pattern is observed in Dannie's generalization reasoning. She started either making no generalizations or using small samples to infer characteristics from an underlying population, and during and after instruction she reasoned at a multi-structural level, using a larger sample to make a generalization and using the distribution of outcomes in some way to assess results. As an example, during Task1PreT she concluded a coin was unfair because the outcomes "should be closer to even." This is evidence of her reasoning at a uni-structural level because although she used the distribution to make a generalization, she did not attend to sample size. During Taks8PostT, after a bottle cap was tossed 10 times she did not make a generalization stating that "it's a small amount of times you flipped it," but after 1000 tosses she said the bottle cap was unfair because the outcomes "should have been closer to be fair" reasoning at a multi-structural level because she is paying attention to the distribution. Dannie's reasoning was observed to be in the highest level (relational) during Task12Ret where she used several aspects of the situation, making connections about the different samples. In general, Lara and Dannie seemed to be able to maintain at least a multi-structural level of reasoning through instruction and post instruction assessments.

	Individual Pre-Test		Individual Pre-Interview		Paired Work with Software During Instruction			Individual Post-Test		Individual Post-Interview		Individual Retention Test	
Task	Task1PreT	Task2PreT	Task3PreI	Task4PreI	Task5Inst	Task6Inst	Task7Inst	Task8PostT	Task9PostT	Task10PostI	Task11PostI	Task12RetT	Task13RetT
Lara	P	P	P	P	U	M	M	M	M	M	M	M	M
Dannie	U	P	U	P	M	M	M	M	M	M	M	R	M
Manuel	U	U	P	U	M	M	R	P	U	M	U	P	M
Brandon	P	P	U	P	M	M	R	P	P	M	U	R	U
Greg	U	P	M	U	M	M	M	U	M	R	M	M	M
Jasyn	U	P	U	P	M	M	M	U	U	R	U	U	P

Table 3. SOLO Levels for Generalization construct before, during and after instruction.

Manuel and Brandon, the average-scoring pair, reasoned at either a pre-structural and uni-structural level during the *pre* tasks and showed an increase in their level of reasoning moving to the multi-structural and relational levels during the instructional tasks. For example on Task1PreT, when given data that a coin was tossed 10, 100, and 1000 times, Manuel generalized the coin was unfair paying no attention to sample size. This is evidence he was reasoning at a uni-structural level. During Task12RetT, when asked how to determine if an odd-shaped button was fair Manuel specified he would have "flipped [the button] 50 times and saw the outcomes." Since he is considering sample size and using the outcomes he was coded as reasoning at a multi-structural level. With Manuel and Brandon the mode of engagement in the task enhanced their reasoning, having a steady performance during the instructional tasks where they worked together as a pair and had access to the software. Their inconsistencies in levels of reasoning on the post tasks indicate that they were capable of reasoning at higher levels (M and R) on some tasks, but that perhaps they did not see the need to apply their understanding of generalization in all tasks.

Jasyn's level of reasoning was often coded as uni-structural, with only two pre-structural instances (Task2PreT and Task13RetT) and one relational instance (Task10PostI). The questioning by the interviewer within this particular task in the post-interview seemed to encourage him to reason at a higher level. His reasoning demonstrated to be stable and higher during the instructional tasks when he was working with Greg. Greg's level of reasoning increased from the *pre* tasks to the instructional tasks. His level of reasoning was mostly uni-structural during the *pre* tasks (with the exception of Task3PreI) and multi-structural during and after instruction (with the exception of Task8PostT and Task10PostI).

Overall, students' reasoning in the generalization construct increased through experience with instruction focused on informal inference. The students were more aware about the importance of sample size and were able to use the distribution of outcomes to make generalizations. They seemed to be recognizing that sampling could be used to gather information that could help them make inferences about an underlying population. Within this construct students reasoned at a higher level during the instructional tasks and the interviews than on individual written assessments.

Discussion

Growth in the ability to make probabilistic inference means for the student to be able to make generalizations beyond the data using an empirical distribution to make predictions about a theoretical probability distribution, recognizing the importance of sample size and types of variability, and, when possible, their abilities to propose an investigation process. All tasks included in the analysis asked students to make generalizations beyond the data; from predicting the distribution of a bag of marbles (knowing the total of marbles as well as how many different colors were in a bag) to estimating the probability distribution of a die sold by a certain company. Some students used their intuitions and ignored the fact that sampling could provide a good estimation about the underlying population distribution (Rubin et al., 2006). Others reasoned and made generalizations based on small samples using the strategies mentioned by Lee (2005) such as the "total weight approach." And others did propose a large sample size, although not always reasoning appropriately about how to use the results to make generalizations about the underlying population,.

Recognizing the importance of sampling and sample size is one of the biggest problems with informal inference (Pfannkuch, 2005). For most of the time, these six students believed that either small or large samples were representative of the underlying population. Even during the instructional tasks, they often used several samples of small sizes to predict the distribution of the colors in the bag of marbles, and to estimate the proportions of Blue Bass fish in the Mystery Fish on a Lake task. Through the study, students used small samples (n=4) and very large samples (n=5000). During the *pre* tasks (Task1PreT through Task4PreI) most of the students were not aware of the importance of sample size in order to draw inferences about the underlying population. Only one was able to recognize it was not appropriate to use a sample of size 10 to make inferences about the underlying population. Five out of six students only used the "total weight approach" discussed by Lee (2005) during the *pre* tasks.

The use of the Probabilistic Inference framework provided insights about how middle school students reason about informal probabilistic inference. The framework could also be used in future research and curriculum development in statistics education that intends to facilitate students' reasoning about important aspects of probabilistic inference, such as, generalization beyond data, variability, and the investigation process. By attending to and coordinating different constructs within informal inference, researchers and teachers may be able to design better tasks, assessment items that facilitate informal probabilistic inference and lead to a better understanding of such reasoning may develop across ages or grade bands.

Introduction

The essence of probability is uncertainty, which lies in stark contrast with the typical problems encountered in mathematics, which are deterministic. Probability can be defined as or framed along a continuum where some things will occur with certainty to the other end of the continuum where some things will never occur. The ability to confront and make decisions under uncertainty is a useful skill in our data rich world in addition to addressing uncertainty within our personal lives. The importance of probability and data analysis as a part of the K-12 curriculum is apparent by its inclusion in the National Council of Teachers of Mathematics (NCTM) *Principles and Standards for School Mathematics* (2000; also see NCTM,1989). Before the NCTM embraced data analysis and probability, early research on probabilistic learning in children, went for the most part, unnoticed by educators, but was embraced by psychologists (e.g., Piaget & Inhelder, 1975).

Earlier research addressed heuristics as a strategy that people used to reduce a complex task into a simpler task in order to assess probabilities or predict values when making decisions under uncertainty (Tversky and Kahneman, 1982a). Later research noted the complexity of reasoning, when people make decisions under uncertainty that extended beyond the heuristics people use as identified by Tversky and Kahneman (Shaughnessy, 2003; Konold, 1988). More recent research addressing the curriculum and the teaching of probability examines the initiatives taking place in the U.S., Australia, and the United Kingdom (see Jones, Langrall, and Mooney, 2007). However, research addressing the probabilistic reasoning of preservice teachers, which curriculum and instructional initiatives depend, is minimal. This study explores the strategies, knowledge, and reasoning of one preservice teacher when engaged in situations of uncertainty.

Theoretical Framework

The dependence on heuristic principles are not limited to lay people, experienced people are also inclined to rely on heuristics when thinking intuitively (Tversky & Kahneman, 1982a). When people struggle to make a decision that consists of lists of possible outcomes, Tversky and Kahneman (1973) found most people try to reduce the complexity of the situation by embracing judgmental heuristics, "a strategy … that relies on a natural assessment to produce an estimation or a prediction" (p. 294), where people "categorize objects and events, which are related to mental models such as prototypes or schemata" (p. 295) that simplifies the situation. They identified and named three types of simplifying heuristics or strategies people use to solve problems, representativeness, availability, and adjustment and anchoring, which may lead people astray.

The representativeness heuristic is used when a person assesses the probability of an event or situation based on how closely it resembles the population. This heuristic comes into play when people are confronted with the following types of questions: "what is the probability that object A belongs to class B? What is the probability that event A originates from process B? What is the probability that process B will generate event A," (Tversky & Kahneman, 1982a, p. 6).

Fundamentally, people make judgments based on the degree that A is representative or similar to B. However, Kahneman and Tversky (1982a) indicate that to be "representative, it is not sufficient that an uncertain event be similar to its parent population. The event should also reflect the properties of the certain process by which it is generated, that is, it should appear random" (p. 35). People view randomness as unpredictable but fair, which means they expect samples to maintain the same or close to the same proportions found in the population.

In addition, Kahneman and Tversky (1982b) indicate that the representativeness heuristic is directional. That is, a person "evaluates the input [or]…predicts the outcome" (p. 57). An example of representativeness given by Tversky and Kahneman (1982b) is as follows; a person is described as a shy, meek, and timid, what occupation would they most likely hold when given the list librarian, doctor, sales person or farmer from which to choose. Most people from their research choose the librarian as the most probable, based on the stereotype of a librarian in our society. Another example, provided by Kahneman and Tversky (1972), involves a maternity ward with five newborn baby boys and two newborn baby girls. The nurses believe the next baby to enter their ward will be a girl so that the number of baby boys and the number of baby girls will even out. The mental model prescribes the probability that a new born baby is a boy is one-half and the probability that a new born baby is a girl is also one-half, which is another way to stereotype. That is, the proportions in samples must be equal at all times or at least remain close to the proportions in the population so that the sample represents the population from which the sample is drawn. Tversky and Kahneman (1982a) warn us that this type of reasoning leads to serious errors because people ignore other factors that impact judgments on probability, such as sample size, prior probability outcomes, illusion of validity, misunderstandings of regression, and misunderstandings of chance.

There are other categories of misconceptions that may arise from heuristics, which include *availability, adjustment and anchoring* (Tversky & Kahneman, 1982a) and the *time axis effect* (Fischbein & Schnarch, 1997) that are beyond the scope of this paper. In essence, the foundational issue revolves around the ability to choose an appropriate strategy when there are tensions that make the decision more difficult. That is, students may wrestle with probability activities due to "(1) fragmented understanding of proportional reasoning, (2) probability ideas [that are] counterintuitive and conflict with students experiences, and (3) … [a student at the collegiate level] experiences probability in an abstract and formal context" (Garfield and Ahlgren, 1988, p. 47). This paper focused on one secondary mathematics preservice teacher as she engaged in several problem solving tasks. This raised our awareness of the complexities associated with her strategies, her mathematical knowledge, and her conceptions about probability, where her reliance on the representativeness heuristic emerged.

Methods

This study used an extended clinical interview setting to explore one preservice teacher's experiences with probability in order to better understand her reasoning when solving probability problems. The interviews consisted of two sessions occurring over a three week period. The interviews involved both an interviewer and an observer. The first author filled the role of observer and took field notes during the interview. The two interview sessions were captured, in their entirety, with the video-audio recorder on the interviewer's computer. The recordings were later transcribed by the observer and later analyzed with her field notes. The transcription from the video-audio was coded first according to the behaviors displayed by the participant when engaged in drawing diagrams, formula calculations, and calculations using diagrams. The next iteration of the analysis involved coding of the data according to the participant's mental processes, i.e., thinking and reasoning. We were interested in the thinking strategies associated with calculations or the ability to recall formulas as well as the reasoning associated with the participant's explanations. The focus of the analysis was then narrowed to the sections of the data where misunderstandings emerged.

Participants

The study drew participants from one mathematics education class consisting of 18 senior mathematics preservice teachers, who intend to teach secondary mathematics. The mathematics preservice teachers attend a large university in one of the Mid-Atlantic States. The demographics of the target population, this class, is diverse in culture and gender, however, the one mathematics preservice teachers who was willing to participate in the extended interview sessions was white and female.

Instruments

There were three instruments used in the study. The first instrument was a pre-test instrument used to identify students who have misunderstandings with probability. The second and third instruments were probability activities. Each of these instruments is described next.

The first instrument was a pre-test that was taken from Fischbein and Schnarch (1997) and it was administered to all 18 preservice teachers in the course. The pre-test instrument consisted of seven probability problems, where the last question had two parts and was entirely open response. All questions except one had three multiple choices answers from which to choose and the remaining item had two multiple choices options. Our instrument was modified from Fischbein and Schnarch (1997) by adding ample space below each question for the mathematics preservice teacher to explain the reason for their multiple choice selection. The questions were designed to identify common misconceptions that emerge when employing the representativeness, negative and positive regency effect, simple and compound events, conjunction fallacy, availability, and the time axis heuristics. The goal of the questionnaire was to evaluate the target population because there was a concern that the mathematics preservice teachers from this target population may not display any of the common misconceptions. Based on the pre-test assessment all but one student demonstrated at least one misconception related to probability. As a result, 17 mathematics preservice teachers were invited to participate in the study. Two mathematics preservice teachers volunteered and this paper examines one of these preservice teachers.

The second and third instruments were tasks used by Shaughnessy (2005). It is the third instrument that is the focus for this study. It is a probability experiment adapted from tasks used by Shaughnessy (2005) called *Coin Flipping – Keep Your Head Up*. The participant explored the probabilities for the various numbers of heads appearing when tossing six coins. The activity is divided into four parts. The first part of the activity has the participant estimating the probability, when flipping six coins that results in six heads, five heads, four heads, and three heads. Following these estimates, the participant performs the experiment recording the results on a tally chart. In the second part of the activity, the participant is asked to make a list of all possible outcomes for flipping six coins. This is followed by the development of a theoretical model for the outcomes of flipping six coins. The third section of the activity has the participant compare the results of the experimental probabilities with the theoretical probabilities, followed by drawing a graph of the experimental and theoretical probabilities.

Procedures

The first interview session began with the preservice teacher sharing prior school experiences with mathematics, attitudes toward mathematics, and attitudes toward teaching mathematics. Following the conversation, the preservice teacher is presented with a probability activity adapted from tasks used by Shaughnessy (2005). As the mathematics preservice teacher solved the problems, she was encouraged to verbalize her thinking and reasoning in detail. The second interview session, which is the focus of this study, had the preservice teacher engaged in a probability experiment based on an activity from Shaughnessy (2005). The activity had three parts.

Results

This study explored the prior experiences with probability and the reasoning of one preservice teacher, Cassie, when engaged in a probability experiment. In the first interview session Cassie explains that she learned probability and statistics by memorizing formulas and definitions.

In the second interview session Cassie was asked to perform an experiment called Coin Flipping – Keep Your Head Up. The activity has three sections that focused on the probabilities of getting various numbers of heads when flipping six coins. The first part of the activity involves estimating the probability, when flipping six coins, of observing six heads, five heads, four heads, and three heads. Cassie wrote down her probability estimates for each of these events and the interviewer noticed Cassie had written $½* ½ * ½ * ½ *½ * ½ = ½^6 = 1/64$ next to the six heads estimate and asked Cassie to explain the method she used to reach that result. Cassie responded:

> Because every time you flip it you have half of a chance of getting it [heads]. So, if you did the tree diagram, you would get heads or tails and then you'd get heads or tails... [and] …there would be 64 choices…and you would have one path with all heads.

The interviewer noticed her response for getting 5 heads was 1/32 and she says to Cassie,

> For 5 heads you [did] the same thing, 1 over 2 to the 5th [or] 1 over 32 … you would say that is one over 32 and another way of thinking about it you'd think [of] all of the paths [so] it would be two over 64, is that what you mean?

Cassie agrees and then explains. "Yeah, because you could do all heads and one tail or all tails, (she stops herself) I'm sorry, or one tail and all heads afterwards". She continues, "I think ….maybe [it's] wrong…hold on" she makes false starts and then begins to draw a tree diagram. The diagram is unclear and incomplete because most of the branches stop short with the fifth coin position. Cassie continues to work and then admits, "Actually I'm confused". After further attempts by the interviewer to help her grapple with these estimates, the interviewer stops this line of questioning and starts Cassie with the coin tossing experiment. She performs the experiment flipping six coins 50 times and tallied the results on the chart. The experiment results are as follows: she tossed six heads once, five heads six times, four heads twelve times, three heads ten times, two heads eleven times, one head nine times, and zero heads once for all 50 tosses. There were no strategies, reasoning's, or calculations involved in this section of the activity, but the interviewer asked her, "What is the probability of getting at least one head"? Cassie replies, "49", which the interviewer responds, "Why would you say that?" She explains, "Because you add up all the probabilities of getting one or more…" The interviewer asks her about the probability of getting at least two heads, which Cassie answers, “You add up 2, 3, 4, 5, and 6 so its 40 out of 50” and follows with the explanation, “because if you get one head it’s not at least two or zero you didn’t get two so you exclude those so you count up all the others that are two or higher”.

The second part of the activity had Cassie generate a sample space of all possible outcomes followed by developing a mathematical model to find the theoretical probabilities for the outcomes of flipping six coins. This time, she neatly draws a tree diagram correctly with all possible outcomes represented. During the conversation, the interviewer randomly selects an end point on Cassie’s tree diagram that showed a branch with three heads and three tails, at which point the interviewer asks Cassie, how many other branches would show three heads and three tails”? Cassie responded, “so half of…so 32”. When the interviewer asked Cassie to explain her answer she replied:

> Every level there’s one head or one tail so if you started with tails, you could (she is thinking and looks confused). Well, I am trying to figure out… if it’s for all 64 possible outcomes … the first one could be either heads or tails, the second one could be heads or tails, so if you just pick …three of them to be tails and three of them to be heads it’s, just a moment let me explain this... or six choose two”?

The interviewer asked her to explain her last comment, “What do six choose two represent”? Cassie is trying to recall the formula for combinations, choosing two out of six, as she incorrectly writes “${}^{6}{}_{2}C_{6}$”. She says, “I haven’t done combinations in a while”. She begins drawing a second diagram showing six short horizontal line segments that represent each position of the six coins laid next to each other. This diagram she drew will be referred as her *slot diagram* in the remainder of the paper. On top of each line segment she writes the numeral two. Cassie continues:

> Ok, so you have six [pennies] and you have two choices, two choices, two choices two choices all the way across for all six of them [she says as she points to each slot]. Then there are…64 different ways you could do it. I think its 32 ways you can have three tails and three heads but, I can’t explain why.

This section of the activity we see her struggle with diagrams and with her partial recall of the combinations formula.

Next, the activity in this section has Cassie develop a theoretical model of the probabilities for the outcomes of flipping six coins, which Cassie struggles at first to understand the task as she looks at her experimental results while considering a theoretical result. She returns to her slot diagram, which supports her and allows her to accurately find the theoretical probability for the event of tossing six heads. Prompted by the observer to next consider the case with zero heads, which is equivalent to observing six tails, she finds the probability of tossing six coins where no heads appears correctly. Prompted by the interviewer she continues this process of addressing the counterpart outcomes. That is, she next finds the probability of one head appearing and then finds the probability of five tails appearing, because it is the counterpart of five heads and one tail. Once she found all of the possible outcomes for flipping six coins, Cassie explains her system using her slot diagram. “If you get a tail in the first one, you have five other places where you can get the second tail”. She continues with three tails, “there are three other places, fourth there are two other places and in the fifth there is one other place. So it would be 15 ways of doing it [referring to four tails and two tails]”. The prompt to consider the complement of zero heads, which is six tails, shifted the conversation to addressing tails, although she understood the same reasoning applied to heads. When asked to find the theoretical probability of getting three heads, she correctly responded with, “I added up 1/64, 1/64, 6/64, 6/64, and 15/64 plus 15/64 and I got 44/64 so that means the rest of the ways for it to have to be 3 heads… and that is 20 over 64”. She used the process of grouping probabilities and using the counterparts of probabilities to fill in all of the probabilities for the various numbers of heads that appear when tossing six coins.

The third part of the activity has Cassie compare the experimental probabilities with the theoretical probabilities. The interviewer asks her to determine “how well do these probabilities agree?” Cassie says, as she is pointing to the theoretical calculations and the experimental results,

> The six heads and the zero heads are pretty close, one out of 50 and one out of 64 for both of those. The same with five heads and one head that’s pretty close, too. Except here, in the theoretical model three heads should have occur[ed] more...but in the experimental, four heads and two heads both occurred more than three heads.

Cassie sees that the experimental frequencies lack the strong symmetry found in the theoretical probabilities. The interviewer closes the session with a final question, “Were there any assumptions that you made when you were doing your experiment”? Cassie responds, “When I did my experimental probability [it] was based on the experiment so, I’m assuming this would always happen in every 50 coin tosses”.

Discussion and Conclusions

This study explores the mathematical reasoning, strategies, and calculations of one mathematics preservice teacher when participating in two probability activities. The activity highlighted her strategies, which include heuristics, diagrams, and incomplete formal knowledge about probability. Cassie’s prior experiences with probability align with other collegiate students who experience probability in a traditional abstract context (Garfield & Ahlgren, 1988).

The second interview session, Cassie performed an experiment called: Coin Flipping – Keep Your Head Up. She was to find the probabilities of various numbers of heads appearing when tossing six coins, which was designed to address the representativeness heuristic. Her attempt to estimate the probabilities associated with six heads, five heads, four heads, and then three heads appearing was problematic for her. She found the probability of getting all six heads by multiplying ½ six times to get 1/64. Her reasoning for the probability of getting five heads with the six coins was 1/32. It appears she focused on the number of heads showing and multiplied ½ that many times ($1/2^5$). This seems to suggest she is finding the probability for five heads using the same process she used for six heads because she knew her model for six heads ($1/2^6$) was correct. This may imply she is using the representativeness heuristic because she used the model for tossing six heads as the model for the tossing five heads, unaware she was changing the problem.

In the second part of the activity Cassie made a list of all possible outcomes for flipping six coins, where she neatly draws a completed tree diagram. The interviewer randomly chooses a branch on her tree diagram, which showed three heads and three tails, and asked her the probability of obtaining three heads and three tails. Cassie responded with 32 but admits she cannot explain why this is the case. It appears she is taking 64 and dividing it in half because out of the six coins, half of the coins would show heads and the other half of the coins would show tails. Another explanation may be that she chose to divide the total number of possible 64 outcomes in half because of the probability of tossing one coin once is one-half. In either case, it suggests she is relying on the representativeness heuristic. We see the tensions between her partial recall of the combinations formula, "${}^{6}{}_{2}C_{6}$", the tree diagram, and the slot diagram, where all of these strategies fail to help her make appropriate estimates of the probability of getting three heads and three tails. Therefore, it appears she relies on the representativeness heuristic to make sense of this problem.

The next activity in part two has Cassie finding the theoretical probabilities for tossing six coins. She struggles at first to understand the question as she looks at her experimental outcomes while considering a theoretical result. She returns to her slot diagram, which supports her and allows her to accurately find the theoretical probabilities for the event of tossing six heads and then, prompted by the observer, to explore zero heads, which is the same as six tails. Cassie explained her system using her slot diagram, where each position of a coin is placed next to each other forming a horizontal row of coins. She explained that a head in the first position allows a second head to appear in one of the remaining five positions, which shows there are 15 ways that two heads and four tails can appear. She continued with this line of reasoning for three heads, where there are three positions possible for the three heads and there are three positions possible for the three tails. The prompt to consider the complement of zero heads with six tails was provided as an aid to reveal the symmetry among the theoretical probabilities, which Cassie was able to grasp. This aid, along with using the complement property of probability, helps her to find the theoretical probability for all of the possible outcomes. When asked of the theoretical probability of getting three heads, she correctly responds with, 20/64.

The third part of the activity has Cassie comparing her experimental and theoretical results, where she sees the experimental results lacked the strong symmetry found in the theoretical model and she notes that the occurrence of three heads is greater in the theoretical model than in the experimental model. The interviewer closes the session with a final question addressing Cassie's assumptions that she may have held prior to performing the experiment. Cassie responds that anytime six coins are tossed 50 times the result would look exactly like hers. This reveals a misconception associated with variability in experiments, which is a common result when someone relies on the representativeness heuristic. That is, people tend to ignore the role that variability plays in sampling.

This study explored one secondary mathematics preservice teacher as she engaged in a probability experiment. The research identified several misconceptions which appear to be associated with the representativeness heuristic. For example, the participant used the same method for finding the probability of tossing six heads, which is ½ multiplied six times, as to finding the probability of tossing five heads by multiplying ½ five times, which is an incorrect assumption. The representativeness heuristic seemed to emerge when she mapped the probability of tossing three heads and three tails to the theoretical probability of tossing one coin once. Additionally, it seems the heuristic emerged when she said that tossing six coins 50 times would result in the same numbers she found in her experiment. Her fragmented formal knowledge, when she tried to recall the combination formula and her struggles to find a useful strategy may have prompted her to rely on the representativeness heuristic. This study proposes that preservice teacher's struggles with probabilities may be a concoction of fragmented formal knowledge, ineffective strategies, and intuitive heuristics, such as the representativeness heuristic. Therefore, future research should focus on the complexity of the problem solving process by teasing out the relationships between fragmented formal knowledge, strategies, and intuitions, which may promote a reliance on the representativeness heuristic, when solving probability problems.

The National Science Foundation MSP Pathways in Environmental Literacy Project is focused on creating learning progressions for environmental science across grade levels 6-12, which includes collecting and analyzing data on students' development of conceptual understanding about the carbon cycle, water cycle, and biodiversity. The Quantitative Reasoning(QR) Theme of the project is researching the impact of quantitative reasoning on students' ability to make informed decisions about the environmental grand challenges facing their generation. This paper will report on findings based on clinical interviews and written assessments of students' QR ability in the context of environmental science.

Pathways in Environmental Literacy is a National Science Foundation Mathematics and Science Partnership project which is establishing learning progressions for environmental science. The learning progressions span 6^{th} to 12^{th} grade, studying the trajectory of learning that leads to the development of environmentally literate citizens capable of making informed decisions. The strands (areas of enduring understanding) selected for study were the water cycle, carbon cycle, and biodiversity. It was hypothesized that comprehension of these three concepts was essential to development of environmental literacy. In addition, three themes were identified as being integral to developing informed environmental decision makers: quantitative reasoning, citizenship, and cultural relevance. The project researchers believe that these three themes must be integrated across the three strands if students are to become informed decision makers. This report will focus on the quantitative reasoning theme.

The Pathways project is a collaboration of six universities, four Long Term Ecological Research Sites (26 LTER sites are funded by NSF to support ecological research on established field sites), and LTER partner school districts. Research teams were established at partner universities to lead efforts on study of the three strands (carbon, water, and biodiversity) and three themes (quantitative reasoning, citizenship, and cultural relevance). Research on quantitative reasoning for the Pathways project was assigned to the University of Wyoming, which had established a Quantitative Reasoning and Mathematical Modeling (QRaMM) research group. QRaMM is one of three research strands initiated by the Wyoming Institute for the Study and Development of Mathematical Education (WISDOM^{e}). QRaMM brings together researchers from multiple universities across the country to share ideas and conduct research on quantitative reasoning and modeling within an interdisciplinary context. As part of the work of QRaMM and in collaboration with the National Science Foundation MSP Pathways in Environmental Literacy Project, a national virtual seminar QRaMM in Science was initiated in Spring 2011. The seminar engaged 15 speakers from across the country in the online video conference, including experts in quantitative reasoning and modeling from the fields of science, computational science, mathematics, science education, and mathematics education. The context for the discussion of quantitative reasoning and modeling was environmental literacy. The issues in psychology of mathematics education for the seminar included students' development of quantitative reasoning and mathematical modeling from 6^{th} to 12^{th} grade, creation of parallel QRaMM learning progressions for those being created by the MSP Pathways project for environmental literacy, and study of the impact and interplay of QR and modeling on students' development of environmental literacy. The national experts informed a QRaMM Science research team consisting of faculty and graduate students who developed Environmental Science QR interview protocols based on MSP Pathways learning progressions. Data from these protocols lead to the creation of Environmental Science QR assessments and research-based professional development that supports learning environments that lead to environmentally literate citizens capable of making informed decisions about the grand challenges facing the next generation.

Purpose of Study

The primary research question for the Pathways project is: What are the characteristics of a 6^{th} to 12^{th} grade learning progression aimed at developing environmentally literate citizens? The purpose of the QR Theme is to determine the quantitative reasoning aspects of the learning progression leading to the primary QR research question: What are the essential quantitative reasoning abilities that are required for the development of environmental literacy? Specific research questions include the following. How does quantitative reasoning integrate and interact with environmental literacy? What is the relationship between learning progressions for quantitative reasoning and environmental literacy – should they be integrated or is a separate learning progression for quantitative reasoning required? What is the current state of quantitative reasoning supporting environmental literacy at the 6^{th} grade level (defined as the lower anchor for the learning progression)? What is the required level of quantitative reasoning for an environmentally literate citizen at the 12^{th} grade level (defined as the upper anchor)? How does the learning progression inform professional development supporting the development of environmental literacy?

Theoretical Framework

The Pathways project is based on the theoretical framework of learning progressions. The Consortium for Policy Research in Education defines learning progressions as follows:

> Learning progressions are hypothesized descriptions of the successively more sophisticated ways student thinking about an important domain of knowledge or practice develops as children learn about and investigate that domain over an appropriate span of time (Corcoran, Mosher, & Rogat, 2009, pg 37).

The panel identified essential elements of learning progressions to be:

- Upper Anchor: target performance or leaning goals which are the end points of learning progression and are defined by societal expectations, analysis of the discipline, and requirements for entry into the next level of education.
- Progress Variables: dimensions of understanding, application, and practice that are being developed and tracked over time.
- Levels of Achievement: intermediate steps in the developmental pathway(s) traced by a learning progression.

- Learning performances: tasks students at a particular level of achievement would be capable of performing.
- Assessments: specific measures used to track student development along the hypothesized progression.

The Pathways learning progressions for environmental literacy are based on research in science education and cognitive psychology, foundational and generative disciplinary knowledge and practices, and strive for internal conceptual coherence. The QR in environmental literacy frameworks build on these characteristics, incorporating mathematical and statistical frameworks.

The Pathways learning progressions have a lower anchor which is the typical accounts of environmental issues given by students at the upper elementary and middle school level (Anderson, 2009). These accounts are empirically tested through a cyclic research process of clinical interviews informing the learning progression and leading to the development of written assessments given on a large scale. The Pathways learning progressions upper anchor is based on experts views of what a scientifically literate citizen should know and be able to do by the 12th grade. The upper anchor is much like a NSTA or NCTM standard, but learning progressions differ from standards in that the lower anchor and intermediate achievement levels are research-based, reflecting the actual trajectory of student learning. A limited number of achievement levels (4 or 5) are identified as plateaus in students' development of more sophisticated ways of thinking about enduring understandings, concepts, and processes. The progress variables for the Pathways project at the meta-level are the carbon cycle, water cycle, and biodiversity, which are considered areas in which students must develop conceptual understanding if they are to become environmentally literate citizens. Within each of these areas progress variables are identified. For example, in the carbon strand the progress variables are generation-photosynthesis, transformation-food chain/web/biosynthesis, oxidation-cellular respiration, and oxidation-combustion. Learning performances are exemplars drawn from the clinical interviews and written assessments which demonstrate student responses at different achievement levels. Learning progression matrices are created by cross tabulating achievement levels (rows in matrix) with progress variables (columns in matrix). A number of learning progressions in science are currently under development including: tracing carbon in ecological systems (Mohan, Chen, & Anderson, 2009), particle model of matter (Merrit, Krajcik, & Swartz, 2008), modeling in science (Schwarz, Reiser, et. al., 2009), genetics (Duncan, Rogat, & Yarden, 2009), chemical reactions (Roseman, et. al., 2006), data modeling and evolution (Lehrer & Schauble, 2002), explanations and ecology (Songer, Kelcey, & Gotwals, 2009), buoyancy (Kennedy & Wilson, 2006), atomic molecular theory (Smith, Wisner, Anderson, & Krajcik, 2006), and evolution (Cately, Lehrer, & Reiser, 2005). Examples of three of these learning progressions are provided in (Corcoran, Mosher, & Rogat, 2009).

The QR Theme of the Pathways project is using the learning progressions theoretical framework to research the impact of QR on students' development of environmental literacy. The overarching goal is to study the capacity of students to understand and participate in evidence-based discussions of socio-ecological systems. Three overarching progress variables are hypothesized: quantitative literacy which consists of arithmetic understandings supporting science, quantitative interpretation which is the process of interpreting scientific models to determine trends and make predictions, and quantitative modeling which is the creation of models by the student. Within each of these areas four progress variables are identified that are hypothesized to be critical QR for science (Table 1).

The development of learning progressions is an iterative process typical of design-based research. The Pathways environmental literacy learning progressions began with hypothetical frameworks based on theories about reasoning about processes in socio-economic systems, including discourse, practices, and knowledge, as well as linking processes between lower and

upper anchors. Challenges for the QR Theme researchers are to determine which of these theories carry over to QR aspects of environmental literacy and to discover potential theories that are more QR-centric. For example, students achieving the upper anchor in the environmental literacy learning progression should function as informed decision makers within the socio-economic system in Figure 1 at three levels: discourse, practices, and knowledge. “Knowledge is embedded in practices, which in turn are embedded in discourses” (Anderson, 2009). We all participate in multiple discourses that associate us with communities of practice (Gee & Green, 1998) and as we gain understanding of a phenomena as our discourse around it matures. The lower anchor discourse for the environmental literacy progression is force dynamic, relying on students' theory of the world with a focus on actors, enablers, actor's purposes, conflicts between actors, and settings for the actions (Pinker, 2007; Talmy, 2003). At the upper anchor scientific discourse is essential, with students moving away from actors in settings to laws that govern the work of systems. Certainly there is a parallel development of mathematical and statistical discourse that is essential for quantitative reasoning. There are four practices that are essential

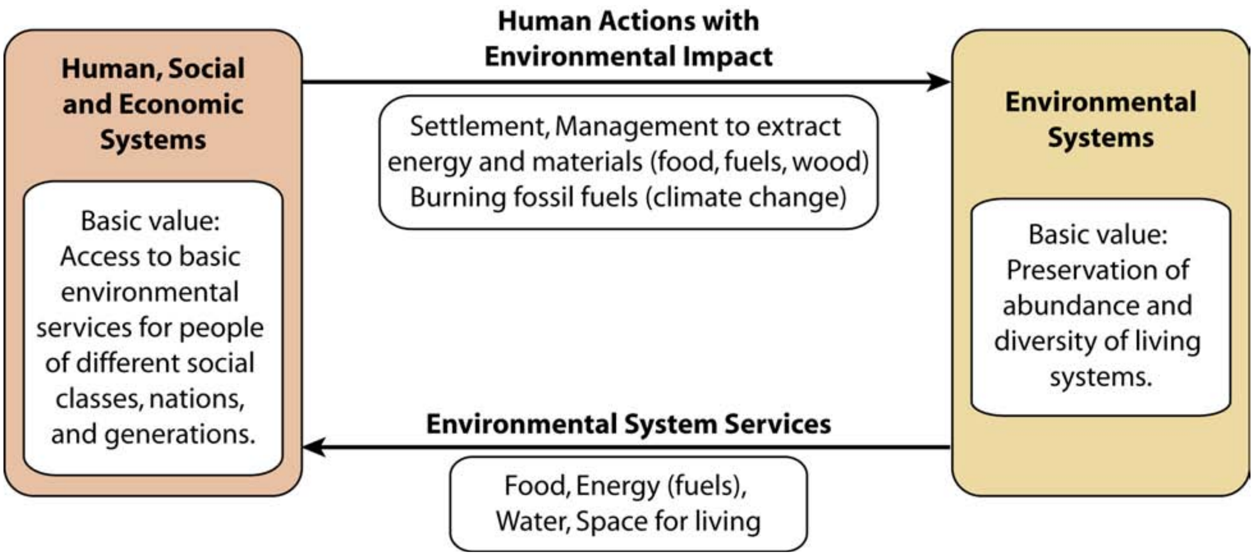

Figure 1: Socio-Economic System

for environmentally responsible citizenship: inquiry (What is the problem and who do I trust?), accounts-explaining (What is happening in the system?), accounts-predicting (What are the consequences of my course of action?), and deciding (What will I do?). At the lower anchor explaining and predicting practices are expressed in force dynamic discourse, while at the upper anchor they are expressed using the language and theory of scientific discourse. These practices reflect the public roles (voter, advocate, volunteer) and private (consumer, owner, worker, learner) roles in which decisions are made. Informed explaining and predicting practices often require QR, which allows for connecting observations to patterns and models, as well as analyzing data from a scientific perspective. Finally knowledge is embedded within discourses and practice. At the lower anchor students focus on knowing facts, while at the upper anchor scientific knowledge is applied to create coherent systems of observations, patterns, and models which serve as the basis for scientific inquiry and accounts. QR parallels this trajectory from knowing mathematical or statistical algorithms to an understanding of enduring concepts that allow one to analyze problems quantitatively.

A framework for the Pathways learning progression consists of progress variables (matrix columns), levels of achievement (matrix rows), learning performances (content of matrix cells),

Carbon-transforming processes	Generating organic carbon	Transforming organic carbon			Oxidizing organic carbon	
Scientific accounts	Photosynthesis	Biosynthesis	Digestion	Biosynthesis	Cellular respiration	Combus-tion

Linking processes	Plant growth	Animal growth	Breathing, exercise	Decay	Burning
Informal accounts	Plants and animals as actors, accomplishing their purposes in life, using their abilities, if their needs (food, water, sunlight, and/or air) are met			Natural process in dead things	Flame as actor consuming fuel

Figure 2: Carbon Linking Processes

and linking processes which are common processes that are recognized by students at all levels of achievement (Anderson, 2009). The carbon framework in Figure 2 provides an example of linking processes within the carbon strand. What are the linking processes for QR? How do they interact with the environmental literacy linking processes? Another aspect of the Pathways learning progressions which is highly quantitative in nature is scaling. Students at the lower anchor often function at a macroscopic or "individual" scale in which they view the world from their sensory purview. Hence, their accounts of environmental issues are based within their daily perceptions at this scale. Moving students to the upper anchor requires that they scale up to a global view, as well as scale down to a microscopic view and even an atomic view. Regardless of the scale, moving up or down the scale becomes intensively quantitative.

Methods

The validation of learning progressions requires conceptual coherence, compatibility with current research, and empirical validation (Anderson, 2009). Conceptual coherence means the learning progression tells a comprehensible and reasonable story of how naïve students develop mastery. Compatibility with current research requires learning progressions to adhere to research on science and mathematics content, pedagogy, and cognition. All learning progressions for QR will be treated as hypotheses which are to be empirically tested. There are five general approaches for hypothesizing progressions: (1) extrapolation from current and conventional teacher and curriculum practice (i.e. standards); (2) cross-sectional sampling of student performance using assessments, observations, or interviews; (3) longitudinal samples of student work over time; (4) closely observed classroom interventions; and (5) disciplinary understanding of the structure of the key concepts in the discipline (Corcoran, Mosher, & Rogat, 2009). The original hypothetical learning progression for QR arose from the first and last approaches, with approach two being the primary method for iterative testing and revision of the learning progression.

Clinical interviews are the initial method of gathering data to validate and revise the hypothetical learning progression. Clinical interviews allow for a deeper insight into student reasoning with faster turnaround for revising the progression. Guiding principles for developing the clinical interviews (Anderson, 2009) are that they are based on the progression framework, built around practices, linking processes, and standard representations, with branching probes to explore discourses, principles, and themes. The interviews are transcribed and coded using the Grounded Theory method. Analysis of the interviews informs the revision of the framework. The revised framework is used to revise the assessment and develop a written summative assessment used to track progress in teaching and learning QR aspects of environmental literacy. Development of the written assessment requires administering them at multiple sites and grade levels across the Pathways project, developing databases of student responses, developing coding rubrics that tie responses to achievement levels and progress variables in the framework, and conducting validation and calibration analysis. Teaching experiments and professional development on QR aspects of environmental reasoning are then conducted, guided by the learning progressions and assessments. The cycle is then repeated.

Results

The QR Theme Team is early in the research cycle. In Fall 2009 through Summer 2010 the QR Theme Team developed QR assessment items to be included in the carbon cycle, water cycle, and biodiversity strands assessments. In Spring 2010 a small sample of students were interviewed using QR items developed for the strands. Based upon initial assessment data piloted in grades 6-12, we hypothesize students function on four different levels: 1) students avoid quantifying the problem even when having a basic understanding of science; 2) students fail to quantify the problem correctly; 3) students quantify the problem correctly but fail to relate it to the science concept; and 4) students quantify the problem correctly and relate it to the science concept. This has led to the development of questions that differentiate on which of these levels students are functioning.

Another observation in the development of assessment items has been the implementation of QR into science concepts where it is not necessary. QR must be incorporated only when it is essential to understanding the science concept. Questions must also be written carefully to illicit informative responses to correctly assess student's QR abilities in the context of science. Specifically, a key element of learning progression assessment items is that they must be open-ended (i.e., must be based on a linking process) allowing for a response from any student. Development of open-ended QR items is particularly difficult, as the QR linking processes must be identified. Simply asking for a numerical response would likely eliminate many student responses.

The integration of QR into learning progressions for ecology has been a challenge. At this stage, we are unsure if the best approach is to integrate learning progressions for mathematical and statistical components of QR into the science learning progressions, to have parallel learning progressions, or if the integration of a learning progression for QR is necessary for the science learning progression. An additional complication is that formal learning progressions for the QR components do not currently exist. Importantly, the data provides an attempt to determine whether the science concepts, the mathematics or statistic concepts or integration of both is the barrier that results in the inability to quantitatively reason about environmental issues.

Discussion

Currently the QR team is working on a number of barriers to the QR aspects of developing environmentally literate citizens. The team believes that QR is not often expressed when students are functioning at the local or individual level, however, as students move across scales up to landscape or down to microscopic and atomic, the need for QR becomes paramount. If students are to become environmentally literate citizens they must address the grand challenges facing their generation, which will require them to scale up to global and down to atomic levels. To address these barriers the QR team is currently working on development of interview protocols, assessments, and professional development rooted in QR in environmental science.

The QR team will pilot global environmental challenges QR clinical interview items in spring 2011. Analysis of data from these interviews will be used to revise the QR learning progressions and explore interrelationships between QR and environmental science learning progressions. Development of a written assessment based on this analysis will begin late in Spring 2011 with the goal of developing a pilot written assessment for use at Pathway LTER sites in Summer 2011. By the time of the PME-NA Conference in October 2011 the Pathways QR Theme Team will have significant data analysis to report.

SEEING COMPLEXITY IN THE PROCESS OF CHILDREN'S BLOCK PLAY

Amy Noelle Parks
University of Georgia
amyparks@uga.edu

Diana Chang
University of Georgia
dchockey21@gmail.com

Nearly a century of research has established a relationship between the complexity of children's block play and mathematical thinking and reasoning in other contexts and in later years. However, most of this research has evaluated complexity by examining children's completed structures. This video-ethnographic study looks at mathematical thinking and reasoning during *block play as a way of contributing to learning trajectory research in early childhood mathematics that values diverse ways of thinking. The paper highlights opportunities for mathematical reasoning that emerged during the construction of "less" complex structures.*

The importance of children's block play for developing spatial thinking and geometric reasoning has been established through multiple studies (e.g., Casey et al, 2008; Guanella, 1934) These studies, dating back almost a century, have looked at ways to increase the complexity of children's block structures as well as ways that this complexity can support more complicated mathematical thinking, particularly in reference to spatial visualization skills, such as imagining flips and rotations (e.g., NRC, 2009). In addition, this body of work has documented relationships between block play and mathematical thinking more broadly (e.g., Caldera et at, 1999; van Nes & van Eerde, 2010). For example, recently Wolfgang, Stannard and Jones (2003) demonstrated a relationship between complex block play at age 4 and mathematics achievement in the 7th grade.

One emerging line of research, developed in response to increased interest in young children's mathematical learning trajectories (NRC, 2009), is the role that teachers can play in scaffolding children's spatial and geometric learning through block play (Clements & Samara, 2007; Kersh, Casey & Young, 2008; NRC, 2009). Gregory, Kim and Whiren (2003) demonstrated that trained educators could support students in creating more complicated block structures by talking with children as they played with blocks. Their study, like most others, evaluated the complexity of the block building through the examination of the qualities of children's completed structures.

The purpose of the current study is to add to this emerging line of research on children's learning trajectories in block play by evaluating children's thinking and reasoning as they go about the process of building with blocks. In doing this work, we hope to contribute to diverse ways of evaluting and scaffolding children's mathematical thinking during block play. Nearly all previous researchers have based their analysis of complexity on the completed block structures. For example, in 1934 Guanella described block structures as ranging in complexity from "pre-organized," where no structure is built, to piles and rows, to solid forms that include closed spaces, to three-dimensional structures (Guanella as cited in Casey et al, 2008). In their recent study, Gregory, Kim and Whiren (2003) expanded on the categories for analysis developed by several previous blocks researchers to evaluate student structures based on three broad categories: the complexity of the building, the complexity of arches, and number of dimensions (use of points, lines and planes) in the finished structures.

We would like to consider the possibility that complex mathematical thinking might not be entirely represented by increased complexity of completed block structures. In other words, a child might set a task for herself in work with blocks on a single plane that is more mathematically complex than one involved in creating a structure on multiple planes. We believe that the documentation of children's learning paths in their work with blocks ought to include an examination of the various cognitive demands and opportunities made throughout the building process as well as documentation of progression in creating more and more complex structures.

Guiding our study were the following research questions:

- What kinds of mathematical thinking and reasoning emerge during children's play with various kinds of blocks in both formal and informal contexts?
- How do interactions with others shape the mathematical thinking and reasoning that occurs?

Theoretical Framework

This study draws on Vygtoskian (1978) traditions that see play as central to children's development and see learning as an outcome of engagement in social activity. In his work, Vygotsky emphasized the tools that children draw on in their learning. These tools include the physical – such as Lego or wooden blocks – and also the social – such as ways of thinking or playing that are learned from other humans in social settings. Although Vygotsky's work around scaffolding is most often taken up to analyze interactions between children and adults, in this study we would like to acknowledge the role that children can play as the knowledgeable others in their peers' play. Particularly, during free time where some children may spend far more time than others with certain materials and thus develop expertise, children themselves may be able to scaffold the block play of their peers toward more complexity. Vygotsky also described the role that a cultural tool like "self-talk" can play in scaffolding a difficult task. He describes a child standing on a chair to reach a cookie, vocalizing each step in the process as a way of managing the difficult task. In a similar way, many children talk to themselves as they play with blocks. Following Vygotsky, we believe it is important to capture and analyze this talk as a way of gaining further access to children's mathematical thinking and reasoning.

Methods

This project is embedded in a larger ethnographic study of children in a rural community as they move from kindergarten to first grade, which seeks to explore their mathematical learning during this time span. As a small, rural school, Taylor County Public School is an ideal site for a longitudinal study because there is only one classroom for each grade. Nearly all of the students who attend the school are eligible for free lunch and about 90 percent are African American. These characteristics make this an important site for broadening the research base on learning trajectories around block-building because much of the reseach on blocks has occurred in settings where a majority of the children are European American and come from middle-income families. Data collection for the larger project includes weekly classroom observations supported by video- and audio-taping, individual video-taped assessment interviews with each child, audio-recorded parent interviews and focus groups, and video- and audio-taped observations of Parent Math Nights. Data collection and analysis for this paper has been informed by the multi-year relationship the first author has with the school.

As an ethnographic study, the research team seeks to understand children's experiences through both observation and participation. For this aspect of the project, this means that rather than comparing students' play and their block structures to pre-existing criteria, we attempted to document the mathematical interactions students engaged in during the process of play. In the preschool classroom, we took fieldnotes, audio-recorded conversations, and documented interactions with video cameras during both formal mathematics lessons and free-choice time, when children were allowed to choose among the many materials in the room, including Lego blocks, wooden blocks, and unfix cubes.

Data analysis was supported by the qualtiative data analysis program NVivo9. Using this program, the research team was able to code excerpts of field notes as well as segments of video clips for analysis. For example, a 30-second video segment could be identified and coded separately from a longer video clip. The observer who recorded the video also used the Nvivo9 program to describe the action going on in the video and transcribe some speech. Initially, data were coded based on the setting, the type of interaction, the materials used, and the mathematical concepts. The current codes are listed in the text box to the right; however, coding, particularly around describing the block play and mathematics, is being continually refined. At the time of writing this proposal, we still have another three months of scheduled observations in the prekindergarten. As a result, the analysis reported in the following section is tentative and still evolving. Over time, we hope to create a map of the opportunities for thinking and reasoning possible in the midst of block play.

Results

In this section, we describe several representative episodes of block play captured by videotape or fieldnotes over the course of the study. These episodes were chosen to demonstrate the mathematical thinking and reasoning that occurred as children interacted with different kinds of blocks, in different settings, and with different people. While all are unique, the kinds of thinking and interactions that occurred in each episode can be found across our data record.

Episode 1: Carter and Wooden Blocks

One afternoon, Carter, who frequently played with all kinds of blocks during free choice time, chose to build with wooden blocks. The block set available in the classroom was relatively traditional, with a variety of rectangular and triangular prisms, cylinders, and arches. On this occasion, Carter decided to build a road out of blocks, announcing his intention to no one in particular. Carter began by laying down a 6-by-3-inch block. He then put together four 3-by-1.5-inch blocks, choosing from dozens of blocks spilling from the tub around him. For the next road segment, he chose two 6-by-1.5-inch blocks, putting them side by side. He then used another 6-by-1.5-inch block and then two 3-by-1.5-inch pieces. Finally, he chose two 3-by-3-inch blocks for the last segment in the road.

The wooden blocks, which were designed to make many equivalent shapes possible, allowed Carter to experiment and practice with composing and decomposing shapes. Carter seemed to embrace this activity as part of his play. After all, several of the large 6-by-3-inch blocks were available and Carter could have chosen to create a road out of identical blocks. Instead, he seemed to go out of his way to make as many equivalent combinations as possible in the building of his road. This ability to compose and decompose shapes has been highlighted as an important mathematical concept for young children because children "who can compose shapes develop better understanding of composing and decomposing numbers" (NCTM, 2010, p. 56) as well as a foundation for geometric concepts. In addition, play like this afforded Carter the opportunity to practice visualization because he needed to orient blocks in the proper direction to make equivalent shapes and to choose the desired block from a pile in the tub.

It is also important to note Carter's intention to build a "road." Traditional rubrics for scoring the complexity of block structures would categorize the road as less complex than other structures because of the lack of vertical building, arches and enclosures. However, this analysis does not take into account Carter's intentional construction of an object that he likely visualized in his head before he created it as well as his efforts to create equivalent segments. In considering complexity, it is important to consider not just the finished product (in this case, a straight line), but also the particular tools used to construct the line (blocks of various sizes and shapes rather than all identical blocks and equivalent block units rather than varyingly-sized units). In this episode, Carter played by himself with little scaffolding from others; however, the available tools contributed to his mathematical thinking. This includes both the opportunities for visualization, identification, composing, and decomposing provided by the blocks, but also the story scaffolding provided by other toys. Casey and colleagues (2008) found that telling stories contributed to children building more complex block structures, and in many ways available toys served this purpose for children in the classroom. For example, in this case, it is unlikely that Carter would have chosen to build a road if cars and trucks had not been available to drive on it.

Episode 2: Markus and Unifix Cubes

One morning toward the end of free-choice time, Markus came upon a bucket of unifix cubes scattered across the carpet. Initially, he bent and began to stack as many as he could into a tower nearly as tall as himself. After holding his tall tower against himself, he sat and began breaking the tower into smaller chunks. He then picked up one of these smaller towers and counted each cube, touching it as he said the number. After counting seven cubes, he reached out grabbed a loose cube and added it on. He then repeated the process, making four other towers of eight cubes each. He then laid these towers against each other on the floor. When he made his fifth tower, he laid it down by the others to check its length and then took off two blocks when he realized it was too tall. At this point, Dahlia and Trevor approached and began to stack the blocks into tall towers. Markus corrected them, saying "We need to make eight! For Bingo." Trevor and Dahila accepted this and began to make towers of eight blocks, each of them counting the blocks in their finished towers one at a time, touching each block and laying their completed towers down next to the pile Markus had made. Other children started to approach, making various lengths with the cubes. Markus reiterated that the towers had to be eight long. At this time the teacher approached and asked Markus, "How many are in your tower?" He picked one up and counted for her, touching each block, "1,2,3,4,5,6,7,8." She replied, "Very good."

Unifix cubes are not often considered in block research; however, as we watched children play with them during the informal moments in the classroom, it seemed odd to exclude them. Because these cubes could only be used as isolated ones or as towers, the mathematical thinking they were most likely to elicit involved counting and comparison. Students compared towers to each other (as Markus did when he was making units of eight), compared them to themselves (as Markus did when he made his first tall tower), and compared them to objects in the room. Students also often counted these blocks, practicing one-to-one correspondence as they did so. Sometimes, this counting seemed to serve a particular purpose, as it did for Markus, who knew that the blocks were passed out in groups of eight for Bingo because the boards had eight spaces. However, more often students seemed to count simply because they had the blocks. This may have been because the teacher frequently used these blocks for counting in formal lessons and also tended to ask children to count the blocks whenever she saw them being used during free-choice time. The unifix cubes seemed to offer fewer opportunities for spatial reasoning than other blocks, although opporutnities to compare lengths did encourage students to talk about more, less, longer and shorter, and to make adjustments to their towers as a result of these analyses. Markus's use of his already constructed towers of eight to measure his new towers demonstrated an ability to reason about length and quantity as he was able to recognize that towers of the same length would have the same amount of cubes without having to count again and was also able to adjust towers by taking off or adding on cubes to get the correct lengths. The task Markus set for himself and the way he set about it reveal aspects of his thinking and reasoning that would not be apparent in the completed pile of towers of eight blocks.

In this episode, the blocks themselves and the potential of a Bingo game later provided scaffolding for Markus to explore length and comparison and to practice counting. Markus, himself, provided this scaffolding for other students, by repeatedly naming the task at hand. Although the other students did not talk about the Bingo game, it is likely that this real-world purpose, served to persuade them to engage in the counting activity Markus set up. On the other hand, the teacher's intervention in this case did little to scaffold mathematical thinking. Markus had already counted the blocks in multiple towers by the time the teacher asked him to count. Indeed, he already knew there were eight blocks in the tower he was holding when she asked him to count the blocks. He performed the task anyway and her response did little to either acknowledge the thinking he had already done or to push him toward new mathematical engagements.

Episode 3: Xavier, Carter and Legos

At the beginning of free-choice time, Carter pulled out the Dulpo Lego blocks. He placed a large blue mat (25 by 25 nodes) on the floor and began to attach blocks along the perimeter of two sides. Nearby, Xavier began to build a tower of 2-by-4 blocks. Once the tower was 10 blocks tall, Xavier attached it to the mat on which Carter was working. Carter rejected this effort, saying "No, I'm making something right here." He reached out and removed Xavier's tower. Xavier accepted this correction and moved away from Carter, who followed him asking, "You want to help me?" Xavier tried one more time to make a tower and attach it, but Carter again removed it from the board. He gestured to the blocks he had placed along the perimeter and said: "I'm doing this." Xavier began to join Carter in filling up the board with a single layer of blocks. This went smoothly until the entire board was nearly full. The boys then began to search for pieces that would exactly fit the few remaining holes. Carter dug through the box to find a 2-by-2 square, which he placed in a matching open space in the center of the board. Xavier turned a rectangular block to fit a remaining hole. The last space in board required a 2-by-8 block; however, one of the surrounding blocks had plastic googly eyes projecting from the side, which made it impossible to fit an appropriately sized block in the adjacent space. After both Carter and Xavier tried a number of correctly sized blocks with little success, they appealed to the researcher observing. She asked them to feel the side of the block with the raised eyes. Xavier did so and then took that block out, replaced it with an identically sized one, and then filled in the last hole before beaming up at the camera. In all, this process took Xavier and Carter 25 minutes.

The Dulpo Legos, with their defined working spaces on mats, primarily rectangular shapes, and ease of fitting together, scaffolded different kinds of mathematical thinking than wooden blocks or unifix cubes. Children were able to build much taller structures with the Dulpo Legos than with the wooden blocks. In addition, the concepts of area, perimeter, and rotations were frequently explored during Lego block play. As Carter did in this example, students frequently created a perimeter first and then filled it in. This required choosing blocks that would be exactly the same length as the mat and negotiating the tricky business of turning corners. Carter, who spent a lot of time in the block area, performed these tasks with certainty, rarely needing to remove a block and replace it with one that had a different length or width, while other children frequently needed to make such adjustments.

These differences in the ways children went about building similar structures reveal differences in development of visualization skills and understandings of length and width and would be unlikely to be captured in the evaluation of a final product. Similarly, in this case, many of the scoring systems for complexity would rank a structure as more complex if it had the tower that Xavier proposed adding; however, Carter's sustained commitment to filling the board demonstrated perseverence with a task and also created an opportunity for both him and Xavier to think about how to fit geometric pieces together exactly, which required anlysis of shapes, lengths and widths and work with rotations. Typically, when children added towers to constructions the play became focused on creating cities or sometimes parking garages, rather than on a task like filling all of the available space on the mat. Thus, Carter scaffolded a more mathematically complex task for Xavier through his commitment to working only in one layer.

Episode 4: Dahlia, Her Mother & Legos

At the Parent Math Night, one of the stations consisted of several boxes of Legos, including special pieces, such as wheels and trees, and written directions for making specific projects. Dahlia came to the event with her mother and her six-year-old sister, Tamara. Her mother took the written directions for a house, held them in front of Tamara, and quietly talked her through the process of building. Dahlia looked on for a moment and then began to build a tower with 2-by-8 blocks. After watching Tamara for a moment, she searched through the box to find window and door pieces the same size as the blocks. She pulled on her mother's sleeve and said "See my house." Her mother looked over, saying, "That's pretty, Dahlia. What you going to do next?" Dahlia pressed her tower onto a Lego board and began to add blocks to her board. After a moment her mother smiled told her to look at Tamara's house, which had a roof, doors, and other accessories, as well as four walls creating the structure. Dahlia looked on for a moment and then began to add additional blocks to her construction.

In this episode, Dahlia, with her mother's help, used her older sister's construction as a model for her own work so that while Tamara constructed a house that mirrored the one pictured in the Lego directions, Dahlia turned her tower into a "house." In someways, viewing the tower as a house was merely cosmetic, such as in Dahlia's decision to add the clear bricks to stand in for windows. However, Dahlia's building of a tower was her independent translation of Tamara's four-walled enclosure. In her attempt to emulate her older sister, she needed to watch what Tamara was doing and decide how to replicate it with the blocks available to her, a process that encouraged the development of visualization skills and manipulation of geometric figures. Her mother encouraged her to add complexity to her structure by prompting her to think about what she should do next and presenting Tamara's house as a model. Unlike the teacher and parapro, both in the classroom and at the Math Night, the parents we observed rarely asked their children to count or to name shapes. Rather, parents scaffolded their children's work and thinking through engagement in the same or similar tasks. For example, the father and son at the table with Dahlia both made their own airplanes. This sort of scaffolding seemed to allow more opportunities for spatial thinking and reasoning to unfold than the teachers' efforts, which continually redirected children back toward traditional preschool mathematics, such as counting.

Discussion

Given the concerns expressed in many recent reports (e.g., NAEYC & NCTM, 2002; NRC, 2009) about the quality of mathematics experiences many young children receive, particularly poor and minority children, we believe it is important to consider ways that opportunities for complex thinking and problem solving can be incorporated into preschool and kindergarten school days in both formal and informal spaces. In the current climate of standardized testing, many early childhood teachers have become focused on basic skills, which has led to a reduction in free play. However new research has shown that these play opportunities are critical for complex mathematical thinking later (NRC, 2009).

This ethnographic analysis of block play raises a number of issues for mathematics educators to attend to as they develop early childhood mathematics curricula, engage in professional development with early childhood teachers, and do further research on young children's learning trajectories. First, it is important to recognize that the complexity of mathematical thinking young children engage in during block play may not be entirely captured in the finished structures. The research community would benefit from increased attention to creation processes, and children and teachers would benefit from increased opportunities to talk about their thinking during and after their work. Second, children's play with blocks needs to be scaffolded to maximize opportunities for mathematical thinking; however, this scaffolding does not always need to come from a teacher in either a formal or informal setting. Well-chosen materials can scaffold particular kinds of thinking, and other children and parents can also support children in problem solving. More research needs to be done on how to build on the strengths parents and children bring to this process. In addition, teachers need to learn both how to watch children during block play to figure out the mathematics that may be present and to recognize the more complex process skills that young children need to develop along with counting and shape recognition. Finally, we would be remiss not to note that in our study, as in much previous work (e.g., Kersh, Casey & Young, 2008), gender mattered in block play. Nearly all of our classroom clips with Legos, wooden blocks, and unifix cubes show the work of boys. However, during Parent Night and in the assessment interviews, girls engaged enthusiastically with the blocks, as Dahlia did in the described episode. Creating spaces where girls were expected to build with blocks and where they did not have to struggle to maintain access to the materials seemed important in giving girls access to these learning opportunities. Guided play as part of formal lessons in classrooms could potentially provide another welcoming space for girls to engage in block play.

Developing learning trajectories around blocks that include both images of what finished structures may look like and descriptions of processes that children go through as they engage with these materials is important to the study of children's early learning broadly and, more particularly, to the study of the relationship between formal and informal learning. Teachers will be able to use these trajectories to learn about the deeper mathematics embedded in block play and to make connections between formal and informal lessons. It is important to both theory and practice to develop these trajectories by looking at the thinking that goes on during block building in a variety of social settings not simply at a progression of completed structures. This theoretical view is likely to be more inclusive of diverse mathematics and of diverse children.

CONCEPTUAL METAPHORS WITHIN MATHEMATICAL PROBLEM SOLVING

Sean Yee
Kent State University
Syee1@kent.edu

Current research in mathematical problem solving suggests that language, and specifically metaphors, are influential in a student's ability to perceive, solve, and learn from a mathematics problem. This paper summarizes the results of a pilot study in which high school students attempted to solve and justify three mathematics problems. The student was video recorded and then allowed to watch himself/herself solving the problems. The student commented on the process used while solving the problems. Three analyses focused on the student's use of conceptual metaphors, the word like (myopic like), and how such factors influenced the student's performance.

Metaphors are a means to relate experiences through language, thought, and action. The relationship between the experiences of the teacher and the student are vital to mathematics education. Specifically, teachers and students share an experiential set: solving mathematics problems. However, the student's and teacher's perspective of what constitutes mathematical problems and/or solutions are complex in structure. (Lakatos, 1976; Lesh & Zawojewski, 2007; Pólya, 1945; Schoenfeld, 1992). Metaphors are culturally designed to make these implicit perspectives explicit. Moreover, they have been found to encourage and incite cognition (Lakoff & Núñez, 2000; Sfard, 1997).

This paper summarizes the results of a pilot study into how metaphors are used in mathematical problem solving, specifically:

Q1. How do metaphors help in understanding a problem?
Q2. How do metaphors guide the process of solving a problem?
Q3. What metaphors are used to describe mathematical problem solving?
Q4. How do metaphors connect problem-solving and proof?
Q5. How can knowledge of conceptual metaphors help teachers improve student learning?

THEORETICAL FRAMEWORK

The theoretical framework for this study has evolved from the firm belief that mathematics is embodied (Lakoff & Núñez, 2000). Fundamentally, embodied mathematics states that mathematics is not mind-free and dependent upon human perception. Concomitantly, this research perceives of mathematics education under the philosophical axiom of cognitive science; one can understand and interpret how people think, and more specifically, learn (Gardner, 1987). Within this realm, this study focuses on the influence of metaphors to one's ability to learn from and solve mathematical problems.

George Polya (1945) emphasized two types of problems in mathematics: problems to find, and problems to prove. This distinction is significant, yet this study will show how these two concepts are not mutually exclusive via linguistics. Another significant area of focus of Polya (1954) was the use of analogies; how analogous problems can be identified and used to solve foreign mathematics problems. This is the springboard from which this article begins because it was through this branch of thought that Polya began to see the influence of language in solving problems.

Polya's linguistic inspiration was paralleled in the 1970's by cognitive scientists, whose emerging field was a culmination of artificial intelligence, cybernetics, anthropology, psychology, philosophy, linguistics (Gardner, 1987), and now education. This interdisciplinarity attracted mathematics educators such as Alan Schoenfeld (1985) to model students' approaches to problem solving. Schoenfeld's attempts to interpret how students solve mathematical problems demonstrated a high level of complexity which suggested a categorization of problem-solving characteristics rather than a sequential how-to model. Schoenfeld's initial categories included heuristics (as reinvented by Polya, 1945), resources, controls, and beliefs. He found that student's expression of their problem-solving process emphasized aspects of control, beliefs, and explicit knowledge of their own cognition. He clarifies this as metacognition, a valuable skill students possess (Schoenfeld, 1992). Combining Schoenfeld's concept of metacognition with Polya's concept of analogy suggests that the language through which students express their cognitive process may demonstrate how students discern between isomorphic (analogous) and non-isomorphic mathematics problems.

The language that the students use to express their metacognition is insulated by experience. In this manner, mathematics is embodied (Lakoff & Núñez, 2000). One's knowledge of mathematics is dependent upon one's perspective and experiential learning of that knowledge. For example, Lakoff and Nunez (2000) demonstrate how the understanding of limit is complex and embodied within one of two conceptual metaphors. One can think of limits graphically; claiming that as x *approaches* (motion metaphor) a number, the function will also *approach* a number. Weierstass viewed limits by saying; if x is within the *proximity* (proximity metaphor) of a number, then the function will also be within the *proximity* of a number. Both metaphorical perspectives are valuable, and distinct in their techniques of proof. However, the logic necessary to solve limit-based problems is analogous in both metaphors. Thus an elusive bond exists between problem solving and proofs in which metaphors are squarely centered (Q4).

Polya's concept of analogy is distant in linguistics from metaphors, yet close in cognition. Analogies reference two concepts already firmly defined in the learners' mind for purposes of mapping aspects of one concept onto the other (Sfard, 1997). However, metaphors frequently model a new conceptual structure with a pre-existing structure. The accommodation of known structures into new concepts can define the new concept, and is considered an aspect of conceptualization (Kövecses & Benczes, 2010; Sfard, 1997). Justifiably, Sfard (1997) refers to such conceptual metaphors as implicit analogies. Hence for mathematical problem solving, application of analogies follows the learner's understanding of conceptual metaphors.

Linguists classify these conceptual metaphors into three hierarchal categories: structural, ontological, and orientational (Kövecses & Benczes, 2010; Lakoff & Johnson, 1980). In all three conceptual metaphors, there is a source domain and a target domain. The source domain is the experientially-known domain and the related concept is the target domain. Thus in the metaphorical linguistic expression "The solution escapes me", the target domain is solutions while the source domain is prey. Hence the conceptual metaphor is "SOLUTIONS ARE PREY". It is important to note that despite the use of the being verb "are", the phrase is unidirectional (Target→Source). Structural metaphors strive to describe a complex concept, such as time, in terms of a concrete experiential object, such as a limited resource, i.e. "Don't waste my time". Ontological metaphors provide target domains with less structure and a new reality in which they may be defined. Personification is regularly ontological; as is the phrase "the solution escapes me". Orientational metaphors are the most difficult to relate experientially according to linguists. They are a broad concept with a specific direction inherent in our development as humans. The metaphorical linguistic expressions "Things are looking up" and "He fell ill" are examples of the conceptual metaphor "HEALTHY IS UP". How these metaphors directly influence a student solving of mathematics problems is the focal point of Q1, Q2, and Q3. Applying this metaphorical influence pedagogically is the purpose of Q5.

RESEARCH DESIGN

This pilot study used a naturalistic paradigm (Donmoyer, 2001) to study how metaphors influenced student's problem solving because the lack of current research within mathematics education (Sfard, 1997) mandates trustworthiness. In tandem, phenomenological inquiry (Short, 1991) was used to search for the essence of mathematical problem solving. Thus, students were chosen according to a list of criteria that indicated the student had a propensity towards mathematics and expressing their thoughts. The population of interest is high school students who are planning on going to college. Characteristics of the sample varied but were limited to participants with a genuine interest in mathematics for learning and recreation beyond grades, participants who could clearly communicate their thoughts without fear of the researcher's judgment, and participants who were willing to make mistakes and continue despite disappointment. Participants were neither included nor excluded based on ethnicity, sex, age, health or association with a special class. Twenty students were asked to participate in the study and nine students volunteered.

Nine students at a suburban high school in Ohio participated: three freshman, two sophomores, and four juniors. There were three females and six males. Each student met with the researcher individually after school for an hour. The students were given the three mathematical problems shown below:

P1. Imagine you had a piece of string. How would you bend this string to make a triangle bounded by the string with the greatest area?

P2. Humans have classified numbers on the number line into two categories, rational and irrational. Rational numbers are those that can be written as fractions, irrational numbers cannot be written as a fraction. Suppose I have an irrational number. If I add one to that number will it be rational or irrational?

P3. How could you cut a cylindrical birthday cake so that you have 8 slices using only 3 straight cuts with a knife?

The techniques and justification for each problem varied mathematically to identify differences or similarities in problem-solving techniques and metaphorical conceptualization. Moreover, the problems were specifically designed to be metaphorically sterile so as to evoke conceptual metaphors from the students without bias. The problems could be done in any order and manipulatives were available to help the students, including cork board, dry erase markers/board, string, pencils, paper, calculators, thumb tacks, pipe cleaners, and straight edges.

As Steffe (1983) poignantly noted in studies involving children solving problems, there are multiple interpretive mediums involved. The experience of the student is expressed by the student, interpreted by the researcher, related via the researcher's experience, and then expressed by the researcher. To minimize the amount of interpretation of the researcher and to maximize the metacognitive expressions of the student, Reynolds' (1993) design was applied where the student would attempt to solve the above problems (primary video) and then immediately watch themselves solving the problems with explicit instructions to explain their thought process (secondary video). Thus students worked with the researcher on the above problems for 30 minutes and then watched the video of their problem-solving process with the researcher for 30 minutes. The names of the students were coded according to the first nine Greek letter of the alphabet.

RESULTS

Using mixed methods, two analyses are complete, while two are still in progress. The first analysis was qualitative and interpreted the student's conceptual metaphors of problem solving. The second analysis was quantitative and ascertained two results; linguistic hierarchy of conceptual metaphors is viable within mathematical problem solving, and the student's use of the word *like* has a negative correlation with their performance on Q1, Q2, and Q3. The third analysis is a continuation of the first two analyses, currently ongoing, and discussed below.

First Analysis: Qualitative

The initial analysis involved multiple observations of all the videos using a phenomenological design and recording significant metaphors, problem-solving techniques, and all justifications. The first analysis revealed that the students evoked metaphors rich in context and culture. For example, when working with P2, Beta stated "Adding rational and irrational numbers is kind of like mixing oil and water". Initially, this analogy helped conceive of the question, but then raised complicated issues when deductive reasoning was needed. A more surprising result of the first analysis was the abundant use of the word *like*. Students used the word *like* frequently demonstrating examples or counterexamples to guide their intuition. When trying to understand the problem, students used the word *like* for inductive reasoning rather than deductive reasoning. The second qualitative analysis delves deeper into these results.

There was significant evidence that a classification of metaphors (structural, ontological, orientational) was applicable to problem solving. Students were consistently able to discuss their problem-solving techniques as if their brain was a separate entity. In the secondary video, students evoked ontological metaphors personifying their mind as an entity from which they were analyzing. For example, Epsilon changed from one question to another because she had to let her "subconscious work on it for a while". Zeta stated "my mind plays games on me." The following is a list of conceptual metaphors (mainly structural) that the students related to their problem-solving strategies through metaphorical linguistic expression in the first analysis:

Table 1: Conceptual metaphors of problem solving.

Target Domain		Source Domain
PROBLEM SOLVING	IS	A JOURNEY, STRATEGIES, A HUNT, A BATTLE, A PRODUCT, A DESTINATION, A BUILDING, A GOAL, TRICKS, DISCOVERY
THE PROBLEM-SOLVING PROCESS	IS	CONSTRUCTING,EXPERIMENTING, ILLUMINATING, TRAVELING, PLAYING, SEARCHING

Notice how problem solving is never personified as a creature with its own intelligence. Yet, the problem-solving process always involves an action-based orientation. For example, no one suggested PROBLEM-SOLVING PROCESS IS THINKING. These results demonstrate a metaphorical system (Kovecses, 2010) with certain coherent (Lakoff, 1980) traits.

Second Analysis: Quantitative

The second analysis (quantitative) had two parts. The first attempted to verify Kovecses's (2010) research in linguistics, that there is a hierarchy between structural, ontological, and orientational metaphors in mathematical problem solving. The second attempted to verify that the frequency of the word *like* was related to the student's performance. It is important to note this voluntary pilot study included only nine participants and thus nine degrees of freedom which limited the study (N<30).

The first part of the quantitative analysis was calculated by counting the number of times each conceptual metaphor was used during the primary and secondary videos. The descriptive statistics are shown below:

Table 2: Descriptive statistics for conceptual metaphors.

Descriptive Statistics	Mean	Std. Deviation	N
Structural	32.22	10.462	9
Ontological	19.78	6.438	9
Orientational	14.78	7.870	9

MANOVA was performed on the data, and the Wilk's Lambda showed a strong significant variability between the conceptual metaphors ($F(3,9)=14.292$, $p=.003$ with $alpha=.05$). Additionally, the structural metaphors were most frequent ($\mu=32.22$) followed by ontological metaphors ($\mu=19.78$) and then orientational metaphors ($\mu=14.78$) as was expected according to cognitive linguists.

The second part of the second analysis demonstrated that the total number of times a student used the word *like* was related to their overall score. For each problem the student solved, but could not justify, the student was given a score of ½. For each problem the student solved and could justify, the student was given a score of "1". Students could receive an overall score between 0 and 3. There was a nearly-significant moderate negative correlation between the overall score and the number of times a student used the word *like* ($r=-.634$, $p=.067$). There was a strong negative correlation to their score on P3 to the number of times a student used the word *like* in P3 ($r=-.937$, $p<.001$). Both of these results demonstrate that the more the student used the word *like*, the worse their solution to the problem.

Third Analysis: Mixed Methods

The third analysis is both quantitative and qualitative and currently still underway. The third qualitative analysis has two parts. First, the analysis develops a metaphorical system (Kovecses, 2010) for problem solving of teachers and students and determines which perceptions of problem solving converge and what perceptions diverge. Conclusions from this study are still being resolved. The second aspect of the third qualitative analysis has yielded results to how the word *like* is used in mathematics by high school students. My study has found that despite the word *like* taking nearly every form of speech, with respect to comparison theory of metaphors, all of the study's participants used the word *like* in only four frameworks.

These four distinct structures were true to mathematics education. Yet, linguistic theories shed light on their interaction within mathematics. Thus before designing a categorization, prototypical metaphors were examined to understand connotations:

Beta: "Adding rational and irrational numbers is kind of like mixing oil and water"
Gamma: "I will treat one side of the triangle like it was fixed"
Delta: "This triangle problem is like extending the rectangle proof"
Iota: "Consider a vector space like three dimensions"

The word *like* was exclusively used within these four instances to clarify the significance of discovery. Other uses of the word *like* did not belong in this classification. Consider the phrase "I was like, 'no way'!" This comparison does not align with the above exemplars because it relates an expression in response to a situation without directly stating the situation. This phrase compares the emotional response which must be assumed by the context. Another use of the word *like* that was never used was "equilateral triangles and the like", making specific reference to a generalizable group of triangles comparable by the equilateral property. Many other uses of the word *like* exist beyond these two, making the results of this study encouraging to mathematics education.

Consider the four exemplars for categorical purposes. Beta used *like* to compare multiple objects and similar operations between the objects. The linguistic structure comparable to Beta's use of the word *like* is an *analogy*; rational numbers are added to irrational numbers as oil is mixed with water. Gamma's conjunctive *like* can be replaced by *as if* which is a common use of *like* to refer to something happening in a literally comparable manner. I will treat one side of the triangle *as if* it was fixed (as literally being fixed). Delta compares the current problem to that of a different problem involving a different shape in hopes of searching for a common process. As these two shapes are unlike in structure, this is best referenced as a *simile*. These three uses of *like* closely resemble comparisons designed by linguist and cognitive psychologist, George Miller (1993). For purposes of interdisciplinary uniformity, Miller's comparison terms will be used here. Specifically, we will refer to the three comparison statements used by students within this study as analogies (Beta), literal comparisons (Gamma), and similes (Delta).

Notice, one can replace Iota's like with the phrase *for example*. This use is referenced in the Merriam-Webster Dictionary (2007) as a possible adjective definition, yet research in linguistics and mathematics education does not mention Iota's use of *like*, despite its frequent use. Iota's use of *like* differs because Iota is emphasizing a specific example (three dimensions) in reference to the broad concept (vector space). Thus Iota narrows, or focuses, to a specific example so as to concretely work with the mathematical problem within a familiar context. Iota's *like* transfers from global to local understanding. This use of the word *like* resembles nearsightedness. This is not to attach a negative connotation to this use of the word *like*, but rather clarify that one focuses on closer (more tangible) objects rather than farther (less tangible) objects. For this reason, I will use the metaphor of *myopia* to reference this use of the word *like*.

Table 3: Comparison Statements of the word *like* in mathematics education.

Like	Structure	Prototypical Example
Analogy	A is to B like C is to D.	Beta: "Even and odd numbers are like rational and irrational numbers."
Literal Comparison	A as if B, or A is literally like B.	Eta: "I was hoping like something would come to my mind".
Simile	A is like B despite A and B being distinctly different.	Gamma: "Get the base of the triangle like the base being the chord of a circle"
Myopia	B is an example of A.	Epsilon: "A quantity can't be irrational like a quantity in real life isn't really irrational because it is a fraction of something."

The purpose of the myopic like was significant and consistent with all students. If a student used the word *like* in solving any of the problems, the myopic like was in attendance. The quantitative analysis of myopias is still under investigation and is not included in these results. Additionally, a larger study (*N*>9) would give a stronger quantitative argument for the significance of myopias.

The lack of research into the myopic model illuminates a crevice between theory and practice. The myopic like has not been studied because mathematics educators perceive this use of the word *like* as misused. The myopic like is improper in formal writing, and thus not studied in how students speak. Yet, its existence mandates linguistic study if we are to rectify student misconceptions. While improper on paper, it is cognitively significant because every participant who used the word *like*, generated a myopia. Moreover, the negative correlation between score and frequency of the word *like* suggests an aid to the practical educator. Students who overuse the word *like* could be focusing on examples and inductive reasoning rather than deductive reasoning. Such a student continues to revolve around tangible examples rather than looking to aspects of those examples that are generalizable (Polya, 1945). Thus educators should be aware that a student's use of the word *like* may indeed cause myopic problem solving without the teacher's help.

SIGNIFICANCE TO MATHEMATICS EDUCATION

This study's primary purpose was to develop and improve upon the understanding of conceptual metaphors within mathematical problem solving. Three conclusions can be drawn from the results of this study. First, students are able to model and describe their problem-solving process metaphorically. Students used personifying ontological metaphors to describe their mind as an external object and structural metaphors to describe how their minds interpreted problem solving and the problem solving process (Table 1). These conclusions offer insight into Q1, Q2, and Q3.

Secondly, the quantitative analysis showed that the linguist's cognitive hierarchy of conceptual metaphors is tenable within mathematical problem solving as the student's metaphorical frequency was greatest with structural metaphors and least with orientational metaphors. This analysis also demonstrated that the more students frequent the word *like*, the lower their performance on mathematics problems that require justification (problems to prove). This negative correlation between the use of the word *like* and the student's performance suggests that if students are unable to move beyond inductive reasoning, they will be unable to deductively reason its logical truth or falsity (Q4). Hence, if a teacher listens for the student's over use of the word *like*, it may be an early indicator that the child is struggling with the concept at hand. The understanding of the word *like* may improve student learning (Q5).

The third mixed methods analysis is still underway, but the results show promise towards two features discovered in the first and second analysis. The third analysis interprets the model of conceptual metaphors for problem solving via a cohesive system for the purposes of helping educators better interpret and teach high school students. Additionally, the third analysis identified four (and only four) uses of the word *like* while solving mathematical problems: analogy, literal comparison, simile, and myopia. The frequent use and discovery of the myopic like suggest more quantitative analysis is needed. Both aspects of this mixed methods study encourage interdisciplinary research between mathematics education and linguistics with the philosophy shared by cognitive science that mathematics is embodied (Lakoff & Núñez, 2000).

This theoretical framework of embodied mathematics demands that pedagogy is influential in mathematics. The metaphors used by teachers and students influence how both parties think and more specifically, learn (Sfard, 1997). This study can aid educators and researchers because it offers specific and tangible observations of cognitive theories, such as conceptual metaphors, the myopic like, and embodied mathematics. The language chosen by students to express and construct mathematical thoughts is not arbitrary. Their ability to use metaphors develops incrementally. The metaphorical hierarchy of conceptual metaphors suggests one such increment, while the myopic like supports another. This analysis has suggested ways in which conceptual metaphors and comparison theory can be used to improve teaching. Hopefully, this pilot study will lead to future studies encouraging and confirming that metaphorical conceptualization can aid mathematics educators and students.

CHALLENGING FACT FAMILY REASONING WITH INSTRUCTION IN NEGATIVE NUMBERS

Laura Bofferding
lboff@stanford.edu
Stanford University

Through "fact family" instruction, students learn the commutative property of addition and inversion principle. However, problems like 3-9, challenge students' understanding of these principles due to their novel arrangement. Sixty-one first graders were randomly assigned to one of three instructional groups. Pre- and post-test interviews indicate that students who practiced operating through zero had greater gains in principle understanding.

Introduction

One of the fundamental goals of elementary mathematics instruction is to help students develop number sense; for children in grades K-2, in particular, number sense involves understanding the composition and decomposition of numbers as well as the relationships among numbers in addition and subtraction problems (National Council of Teachers of Mathematics, 2000). An important part of this process includes learning three principles: the commutative property of addition (e.g., 4+5 = 5+4), the inversion principle (e.g., 4+5=9, so 9-5=4), and the subtraction complement principle (e.g., 9-4=5 so 9-5=4). Knowledge of additive commutativity tends to appear before the other two principles, with inversion presenting more difficulty for young children (Canobi, 2005).

Instead of only addressing these part-whole relationships individually, US textbooks frequently incorporate a series of lessons on "fact families" which aim to help students see these connections all at once (Lovin, 2006). In the California version of the first grade *enVision* mathematics curriculum, there is one lesson dedicated to the commutative property of addition and seven lessons on relating addition to subtraction and using "fact families" (Pearson Education, Inc., 2009). Although the use of "fact families" or "turn-around facts" as an instructional focus seems widespread, there is little research on their effectiveness. Because studies show students understand that 4+5=5+4 and teachers see students correctly filling in the "fact families", we might believe that students *do* understand all of these principles; however, other studies show that students solve problems like 62–48 by subtracting the smaller number from the larger number in each column, regardless of their placement (Fuson, 2003). These results suggest that students may not have full understanding of these principles. This paper takes a small step at exploring how early instruction in negative numbers might facilitate first grade students' judgment of when and how to use the commutative property and inversion principle.

Theoretical Framework

As children learn addition and subtraction and develop more efficient strategies for solving arithmetic problems, they move through three "conception of quantities" levels (and sometimes a transition level) (Fuson, 1992; Murata, 2004). At Level 1, students count all quantities; for 3+4 a child would count out three objects, count out four objects, and count the combined collection to find the total. Students at Level 2 shorten this process by counting on (or counting back or up for subtraction); for 3+4, this student would say "three", knowing that it is not necessary to count out the three, and then count on "four, five, six, seven." Finally, at Level 3, students use composition and decomposition methods, especially involving groups of ten, to solve problems. Learning and using these part-whole relationships, such as those emphasized with fact families, is one of the most important goals in elementary arithmetic (National Research Council, 2001).

Aside from guiding students towards part-whole strategies, effective mathematics instruction also needs to help students develop mathematical proficiency: conceptual understanding, procedural fluency, strategic competence, adaptive reasoning, and productive disposition (National Research Council, 2001). According to the National Research Council, "Examining the relationships between addition and subtraction and seeing subtraction as involving a known and an unknown addend are examples of adaptive reasoning" (p. 191). Along with fostering adaptive reasoning, presenting all forms of a fact family together (e.g. 4+5=9, 5+4=9, 9-5=4, and 9-4=5) might also help students deepen their *conceptual understanding* of the commutative property, subtraction complement principle, and inverse principle as students make connections among these relationships. However, by spending limited to no time learning the principles separately, it is also possible that rather than understanding these complex relationships, students learn that order does not matter for addition and likewise assume that the numbers in subtraction problems can be moved around in multiple ways.

A more *procedural understanding* of these principles could lead students to incorrectly think they can solve 2–7 as they would 7–2 by misapplying the commutative property or by thinking, "What plus 2 equals 7?" due to a misapplication of the inversion principle. Alternatively, students may use these misapplied methods because they do not know about negative numbers but feel the need to provide an answer anyway. Students who know about negative numbers and their relationship to positive numbers may be willing to think about obtaining answers other than positive numbers. Furthermore, learning that the commutative property does not hold for subtraction and having experiences correctly solving subtraction problems with smaller minuends might help these students better understand both the commutative property and the inversion principle.

Research Questions

The following questions guided this analysis:

1) How do students reason about the commutative and inversion properties before and after instruction in negative numbers?

2) How is instruction on the order and value of negatives and/or addition and subtraction with negatives related to students' understanding of commutativity and inversion?

Methods

Subjects and Site

This data comes from a study conducted at an elementary school in northern California, in which 47% of its students are English language learners (California Department of Education, 2010). Out of a possible 79 first graders at the school, 61 first graders (30 male, 31 female) agreed to participate and complete the interviews in English. The study took place in the spring, so the first graders had already learned about addition and subtraction.

Materials and Data Collection

The study employed a pre-test, post-test design with an instructional intervention. Both pre- and post-tests were conducted as individual interviews and involved similar questions; some post-test problems were identical to those on the pre-test, while others just had different numbers. During the interviews, students were asked to explain how they solved the problems.

While the questions covered a wide-range of integer concepts, including addition and subtraction problems, this paper focuses on a small-subset of question categories: counting backward, integer value comparisons, commutative property, and subtraction problems. Table 1 lists the questions from both the pre- and post-tests.

Table 2. Items students completed during the pre-test and post-test interviews.

Question Category	Pre-Test	Post-Test
Counting backward	"Start at five and count backwards as far as you can. Is there anything before <last number child says>?"	"Start at five and count backwards as far as you can. Is there anything before <last number child says>?"
Integer value comparison *"What are these two numbers? Circle the one that is greater."*	8 vs. 6*	6 vs. 4*
	3 vs. -9	5 vs. -7
	-2 vs. -7	-3 vs. -1
	-5 vs. 3	-8 vs. 4
	-8 vs. -2	-6 vs. -2
"Two children are playing a game and trying to get the highest score. Circle who's winning."	4 vs. -7	5 vs. -9
	-7 vs. -3	-8 vs. -6
Commutative property *"Just look at these two problems. Do you think they will give you the same or different answers?"*	4 + 5 vs. 5 + 4	2 + 5 vs. 5 + 2
	3 – 1 vs. 1 – 3	4 – 1 vs. 1 – 4
	6 – 4 vs. 7 – 4 (distracter)	7 – 3 vs. 7 – 4 (distracter)
	5 – 8 vs. 8 – 5	2 – 9 vs. 9 – 2
	3 + 2 vs. 3 + 3 (distracter)	6 + 3 vs. 2 + 6 (distracter)
	9 – 6 vs. 6 – 9	0 – 8 vs. 8 – 0
Subtraction *"Solve this problem."*	1 – 4 =	1 – 4 =
	3 – 9 =	3 – 9 =
	6 – 8 =	6 – 8 =

*All students solved these problems correctly, so they were excluded from further analysis.

After the pre-test, students (regardless of classroom) were randomly assigned to one of three instructional groups, so that each group had an even mix of students (in terms of initial understanding of negative numbers, teacher ratings of their math performance, and gender). Each group participated in 8, 45-minute lessons. During their group's instructional time, students met in a separate room, and the author provided instruction. Group 1 (N=20) received instruction on the order and value of negative numbers along with how to add and subtract with them; this included learning that subtraction is not commutative. Group 2 (N=21) only received the "adding and subtracting" lessons from Group 1's instruction, without learning about the order and value of negatives, while Group 3 (N=20) only received the "order and value" lessons from Group 1's instruction. Both Group 2 and Group 3 had additional practice games similar to their original lessons so that they received the same amount of lesson time as Group 1. Table 2 provides an outline of the lessons for the three groups.

Table 3. Lesson topics for the three instructional groups.

	Day 1	Day 2	Day 3
Group 1 (N=20) Integer Value & Order, Add, Subtract	Discuss and explore symbols	Explore minus sign versus negative sign	Vertical number line with integers; Game: Which is greater?
Group 2 (N=21) Add, Subtract	Explore lack of commutativity for subtraction compared to addition, no specific mention of negatives		
Group 3 (N=20) Integer Value & Order	Discuss and explore symbols	Explore minus sign versus negative sign	Match negative numbers vs. positive numbers

	Day 4	Day 5	Day 6	Day 7	Day 8
Group 1 (cont.)	Explore commutative property and lack of commutativity for subtraction compared to addition		More (move right) vs. Less (move left)	More positive = larger, more negative = smaller	Less positive = smaller, less negative = larger
Group 2 (cont.)	More (go right on NL) versus Less (go left on NL)	More positive= larger, more negative= smaller	Less positive= smaller, less negative= larger	More positive, less positive, more negative, less negative	
Group 3 (cont.)	Negatives on a vertical number line; Game: Which is greater?		War: Which integer is Greater?	Game: Get three or four consecutive integers in a row	

Analysis

Students' solutions were coded for number correct in each category, and their verbal reports were transcribed for each. When counting backward, students only had to count to "negative one" in order for their count to be considered correct. Using the terminology "minus one" or "penalty one" also counted. Regarding the commutative property questions, all distracter questions were removed from this analysis (only three students gave an incorrect answer for one or both of these). Students' explanations were coded based on their reasoning for why they thought the answers would be the same or different (e.g., Commute = commenting on the numbers being switched around, Inverse = justifying a subtraction problem based on an addition problem). Finally, for the subtraction problems, answering "0" or a negative number was counted as correct since these answers meant students were not reversing the order of the numerals, which was all the study explored. The explanations of students' solutions were coded as to whether they reversed the numbers or used inversion reasoning in solving the problems.

Results

Table 3 lists each group's percentage correct scores on the pre- and post-tests for each question category, along with their overall percentage gains. On the counting backward and integer value comparison tasks, both groups who had instruction on integer order and values (Groups 1 and 3) made pre- to post-test gains that are almost double the gain of Group 2, who did not receive this instruction. Unsurprisingly, on the pre-test, all groups demonstrated understanding of the commutative property of addition, judging that 4+5 would give them the same answer as 5+4; because of their high initial performance on this item, there were small to no gains on this item across groups.

When asked if subtraction problems and their reversals would give them the same answer, Group 3—who learned about the order and value of negatives—made a large gain in understanding that the answers would be different. However, when they were asked to solve the problems, they made no gain in providing negative or zero answers. On the flip side, Group 1—who received instruction in all of the topics—made no gain in identifying that the subtraction problems with smaller minuends would have different answers but made a modest gain in actually providing negative or zero answers when they had to solve them. Group 2—who practiced adding and subtracting on both sides of zero—improved on both of these question types.

Table 3. *Percentages correct (and gains) for each group on pre- and post-tests by question type.*

Counts Backward into the Negatives	**PreTest (%)**	**PostTest (%)**	**% Gain**
Group 1 (N=20)	15%	60%	**45%**
Group 2 (N=21)	14%	38%	24%
Group 3 (N=20)	20%	65%	**45%**
Correctly Compares Integer Values	**PreTest (%)**	**PostTest (%)**	**% Gain**
Group 1 (N=20)	18%	73%	**55%**
Group 2 (N=21)	17%	32%	15%
Group 3 (N=20)	20%	90%	**70%**
Commutative Property of Addition	**PreTest (%)**	**PostTest (%)**	**% Gain**
Group 1 (N=20)	85%	95%	10%
Group 2 (N=21)	90%	95%	5%
Group 3 (N=20)	90%	90%	0%
No Commutative Property of Subtraction	**PreTest (%)**	**PostTest (%)**	**% Gain**
Group 1 (N=20)	37%	32%	-3%
Group 2 (N=21)	11%	37%	**25%**
Group 3 (N=20)	15%	48%	**33%**
Solving S – L, where L>S, S, L > 0	**PreTest (%)**	**PostTest (%)**	**% Gain**
Group 1 (N=20)	33%	45%	12%
Group 2 (N=21)	38%	63%	**25%**
Group 3 (N=20)	47%	45%	-2%

Students' Responses

While Group 2 was the only group to show growth for both the commutative questions and the subtraction problems, there were similar trends and student variation in each of the groups. Over all groups, students reversed numbers to solve 3-9, 6-8, and 1-4. An additional nine students specifically misapplied inversion reasoning to justify their positive answers; this is likely an underestimate since several students provided positive answers without justifying why they did so. Each group had at least one student who originally claimed problems such as 3-9 and

9-3 would have different answers but then on the post-test stated they would have the same answers. Furthermore, each group had students who demonstrated no gains from pre- to post-test (although some of these students changed their reasoning about their answers). Finally, all groups contained students who improved in realizing that the subtraction problems would give them different answers, and more specifically, that subtraction problems with smaller minuends would not have positive answers. See Table 4 for examples of how students in these subsets reasoned from pre- to post-test. The examples are from students in Group 1, but their reasoning is reflective of the other groups' reasoning.

Table 4. Examples of students from Group 1 whose performance decreased, stayed the same with different reasoning, and improved from pre- to post-test.

ID	Test	Answer	Explanation	Code
209	Pre-Test	3 – 1 ≠ 1 – 3	Three and taking one is (writes 2). There's one and you took away three and there's no more, and it's zero (writes 0).	Zero / Positive
	Post-Test	4 – 1 = 1 – 4	Four. Four. One. One.	Same Numbers
213	Pre-Test	3 – 1 ≠ 1 – 3	When you minus, it can't equal the same number.	Not Equal
	Post-Test	4 – 1 ≠ 1 – 4	This one [1 – 4] would equal a negative and this one [4 – 1] would equal a positive number.	Negative/ Positive
101	Pre-Test	3 – 9 = 6	Six plus three is nine.	Inversion
	Post-Test	3 – 9 = -6	(counted back on fingers) Two, one, zero, negative one, negative two, negative three, negative four, negative five, negative six.	Count Through Zero

Discussion and Conclusions

While all of the groups improved in a couple areas, some of the findings are clearer than others. The differential instruction influenced students' improvement on certain questions due to their emerging understanding. The two instructional groups who learned about the order and value of negative numbers (Groups 1 and 3) had greater gains on the counting backward and integer comparison tasks. This is unsurprising since students in these groups practiced counting backward through zero and played games which focused on the value of integers. Group 3, on the other hand, only saw negatives written on a number line in one lesson, and the numbers were not named or pointed out to them.

As found in previous studies, these first graders also showed consistent knowledge of the commutative property of addition. The patterns for the subtraction problems with smaller minuends are less clear. Group 2 showed gains in identifying that subtraction problems, when reversed, will result in different answers; they also made gains applying this knowledge in order to solve the subtraction problems. They transitioned from giving positive answers to answering mostly negative numbers or zero. During instruction, this group spent several lessons playing games where they moved back and forth across zero as they acted out addition and subtraction problems. These motions may have facilitated their developing conceptual understanding of why the answers would be different and helped them avoid the perceptual inclination to think that commuting in subtraction is okay because the problems contain the same numbers.

Group 1, however, also received this movement instruction, but their gain was much smaller than Group 2's. A possible reason for this is that Group 1 spent less time on the addition and subtraction activities because they also had lessons on integer values. It is reasonable that the length of time students practice moving beyond zero is related to their ability to reason about why subtraction problems with smaller minuends would have different answers than their reversals. The results of this study only hint at a possible connection, but further study is needed.

Although Group 1 did slightly improve in concluding that the subtraction problems with smaller minuends would not be positive, they did not improve in judging that subtraction is not commutative. How can we account for these contradictory results? On the one hand, more students in this group started with knowledge that subtraction is not commutative compared to the other groups, so they had less room for growth. On the other hand, four of the students had lower performance on the post-test, so it is possible that the combination of both types of instruction was too much to keep straight in such a short period of time. Again, investigating instruction over a longer time period or with slightly older students who may be better able to integrate the many aspects of the lessons may provide insight into this issue.

Finally, while Group 3 showed gains in identifying that subtraction is not commutative, they did not make any gains in applying this knowledge. Over half of the students could count into the negatives, yet they did not use this strategy to solve the subtraction problems. Furthermore, two students stated that subtracting a larger number from a smaller one would be a negative number, yet they still wrote positive answers to the subtraction problems. One possible explanation for this result is that students are used to inverting problems from working with fact families, and they continue to invert even in contexts where this application is incorrect—even if they know it!—since they did not have the experience (as Group 2 did) breaking out of this habit.

A second possible explanation is that students may be able to operate at Level 3 of the conception of quantities either on a procedural/perceptual level *or* on a conceptual level. One hypothesis was that students in Group 3 should have been more willing to get negative answers because they had instruction in their existence. However, they also may have had a surface understanding of the commutative and inverse properties—believing that one can change the order of the numbers in any way. Since they did not have instruction in solving negative problems, students in this group may have felt it easier to use one of the properties they "knew"—such as "switching" the numbers—rather than attempting to solve the problems in a new way.

Clearly, the results of this study raise more questions than provide answers, and we need to investigate children's learning of the commutative and inverse properties further. However, one noteworthy finding is that if children have knowledge of the commutative property of addition this does not mean that they understand its limits. A stronger argument could be made for the inversion principle. By using 2+3=5 to solve 3-5, children demonstrate that the numbers, rather than their order and relationship to each other are more salient features to them. These results suggest that students will develop deeper conceptual understanding as well as the flexibility to know when they can apply learned rules and reasoning by having experiences with those situations which require them to expand or challenge their original understanding. If we can help students develop deeper schemas for concepts and procedures earlier, they will have a stronger mathematical base on which to build future concepts.

SUPPORTING FRACTION-BASED ALGORITHMIC THINKING: PAVING THE WAY VIA ESTIMATION AND NUMBER SENSE

Debra I. Johanning
The University of Toledo
debra.johanning@utoledo.edu

This report shares early findings from research on teacher practice associated with fraction-based algorithmic thinking. It describes key practices used by a "skillful" experienced sixth-grade teacher while implementing a curricular unit that leads students to develop algorithms for fraction operations using a guided-reinvention approach. These practices emerge from the initial days in the unit where estimation and number sense are the focus of lessons that set up the work to come where students will be developing algorithms for operating with fractions. These practices highlight mathematical thinking patterns, representations and language development that this teacher emphasized.

Purpose

Many have discussed the work of teachers and how the practices a teacher draws upon directly influence what students learn. In their review of the collective literature on teaching and classroom practice, Franke, Kazemi and Battey (2007) offer that effective teaching involves more than having a rich task or eliciting students' thinking. How one orchestrates mathematical discourse in a particular mathematical domain needs more attention. For example, what is it that a teacher should attend to when they elicit students' thinking in a particular domain? What are the core activities that should occur regularly when teaching in a domain? The research findings reported here are from a larger study focused on examining teacher practices that support students to engage in algorithmic thinking (Gravemeijer & van Galen, 2003) associated with fraction operations. In this research report I draw from the work of one of four experienced "skillful" teachers whose practice is being studied. The focus is on the initial days of an instructional unit where students will be developing algorithms for adding and subtracting fractions. This teacher's local instructional theory (Gravemeijer, 2004) for using estimation in preparation for developing approaches for finding actual sums will be presented and examined in terms of mathematical thinking, representation and language development.

Theoretical Framework

In their discussion of an *emergent modeling-reinvention* or *guided-reinvention* approach to algorithm development, Gravemeijer and van Galen (2003) emphasize that when instruction emphasizes algorithmic thinking based on student-generated approaches, that students engage in generating and developing their own mathematical knowledge. A guided-reinvention approach to algorithm development relies on teachers who have topic-specific instructional theories to organize the emergent ideas of their students around.

> A local instructional theory describes, with arguments, how enacting a series of instructional activities can support a specific long-term learning process. It would for example, describe how children first learn informal ways of addition and subtraction and how they may thereby develop more standard procedures for addition and subtraction. Or it would describe how children develop calculation procedures that may or may not be similar to the standard algorithms for multiplication or division. (Gravemeijer & van

Galen, 2003, p. 117)

This research seeks to make explicit such theories and the supporting arguments that guide the instructional choices that teachers make when positioning students to developing meaning of and algorithms for each fraction operation.

Gravemeijer (2004) argues that “if justice is to be given to the input of the students and their ideas built upon, a well-founded plan is needed” (p. 126). He distinguishes between Simon’s (1995) *hypothetical learning trajectories* used to plan instructional activities and *local instructional theories* which provide a rationale for an “envisioned learning route as it relates to a set of instructional activities for a specific topic” (p. 107). Drawing from Simon’s (1995) travel metaphor Gravemeijer suggests that a local instructional theory offers a travel plan with a destination that is steered toward as teachers choose instructional activities and design hypothetical learning trajectories for their own students. An important point made by Gravemeijer is that local instructional theories can never free teachers from having to design hypothetical learning trajectories for each class of students they work with. In the work presented here, project teachers were using a particular curriculum unit, Connected Mathematics Project II (CMP II) *Bits and Pieces II: Using Fraction Operations* (Lappan, Fey, Fitzgerald, Friel & Phillips, 2006) which focuses on developing meaning for operations, allows algorithms to arise through student engagement with contextual situations, and explicitly asks students develop algorithms for each of the four fraction operation. The curriculum is viewed as an initial hypothetical learning trajectory or travel plan. It provides a place to start. However, the exact path of travel involves how the teacher uses the provided curriculum, including alterations that they make to the curriculum, and the students’ ideas that emerge.

Reasoning and proof is an important part of the guided-reinvention approach. Regarding reasoning and proof, Ball and Bass (2003) offer two foundational ideas related to practices of teaching mathematics: developing a base of public knowledge and the development of mathematical language. A practice that supports student to engage in reasoning and proof should take into account how ideas are developed visually, what ideas are made public, how ideas are identified and preserved, and how to use records of practice to support the development of new ideas. In the data presented, the use of representational records and how they are used to support the development of mathematical language is highlighted.

Kazemi and Stipek (2001) suggest that implementing reform-minded mathematics instruction is challenging. In their research (summarized in Figure 1) they found that teachers whose practice regularly incorporated sociomathematical norms, rather than the general social norms associated with mathematics reform, involved a higher press for conceptual thinking on the part of the students. They offer that teachers need to “understand what a sociomathematical norm is and construct pedagogical strategies for can be applied in a variety of contexts” (p. 79). Closely related to the work on sociomathematical norms is the ability of a teacher to sustain the level of cognitive demand (Stien, Smith, Henningsen & Silver, 2000) when implementing instructional tasks.

Figure 1. Related Social Norms and Sociomathematical Norms

Social Norms	Sociomathematical Norms
Students describe their thinking	An explanation consists of a mathematical argument, not just procedural description
Students find multiple ways to solve a problem and share their strategies with classmates and teacher	Mathematical thinking involves understanding connections across multiple strategies
Students can make mistakes—this is a normal part of the learning process	Errors provide opportunities to reconceptualize a problem
Students collaborate to find solutions to problems	Collaborative work involves individual accountability and reaching consensus through mathematical argumentation

The contributions of those like Ball and Bass (2003) or Kazemi and Stipek (2001) are acknowledged as important. However, building upon the call by Franke, Kazemi and Battey (2007) to identify key routines of practice associated with a particular mathematical domain, this work seeks to extend such contributions. Teachers need to develop local instructional theories about fraction algorithm development as part of determining what is involved when deciding what ideas to develop visually, what ideas to make public, how to address misconceptions that emerge, what records of practice would be useful, etc., as one navigates. One might envision a third column added to the chart in Figure 1 that fleshes out the intersection between socio-mathematical norms and supporting students to engage in algorithmic thinking associated with fraction operations.

Methodology

The findings reported here draw from the work of one of the four teachers during the initial lessons in a unit on fraction operations. This teacher is using the Connected Mathematics Project II (CMP II) curricular unit *Bits and Pieces II: Using Fraction Operations* (Lappan, Fey, Fitzgerald, Friel & Phillips, 2006) as the primary curriculum. Having taught mathematics using a reform-based approach for approximately 15 years, he adjusts or modifies the curriculum as needed for his students. He draws from his past experience with learners as well as what is happening with the current group of students he is teaching. He is true to the mathematical intent of the curriculum but as is the case with the lessons examined for the findings reported here, he has redesigned some of the lessons, or parts of lessons, for very specific reasons. This is an important characteristic of the four teachers who were studied—they each have a personal perspective on what experiences students need to participate in if they are to move toward articulating algorithms. For this teacher and the others, the adopted curriculum is a tool used in conjunction with what they know about how students make sense of and come to articulate fraction operations.

This study uses a qualitative design. The primary data sources were video of daily lessons, audiotaped reflections by the teacher on the daily lesson, weekly debriefings with teacher and responses to structured interview questions. The analysis was guided by Erickson's (1986) interpretive method and participant observational fieldwork, which addresses the need to understand the social actions that take place in a particular setting. The analysis of this teacher's practice, along with the articulated reasoning that emerges from reflections and interviews is an important part of understanding his local instructional theory. Identifying and classifying the teacher's declarative statements and questions posed during lessons, served as the initial starting point for articulating themes. The findings reported here focus on the prevalent mathematical reasoning patterns, representational development (diagrams as well as written symbolic) and the mathematical language being supported in the initial 3½ days of a unit where estimation and number sense are the focus of lessons that set up work to come developing algorithms for adding and subtracting fractions.

Findings

A majority of the coded classroom dialogue involved the teacher asking questions of students as they worked on problems in small groups and when they presented their work in whole class discussion. When the teacher asked a question a response was expected. While the teacher did ask some generic questions that positioned students to work together (i.e., "Did someone try this a different way?" or "Does somebody in their group think they can help?"), most of his questions served specific mathematical purposes. His declarative statements were designed to draw out particular mathematical ideas and reasoning patterns. Statements often supported students to develop a written record or a representation that captured their thinking. Figure 2 summarizes the major themes found in the class transcript data.

Figure 2. Major Themes and Number of Occurrences across 3½ Days of Instruction

Questions that…	Declarative Statements that…
Explicitly or implicitly assessed or developed meaning for numerator and denominator (17)	Purposefully drew out students' thinking to make it evident for all (4)
Assessed or pushed for development of how far a fractional quantity is from 0, ½, or 1 whole (29)	Prompted for or pointed out that reasoning needs to be provided—an answer without reasoning is not valid (12)
Prompted students to articulate their understanding of how to estimate (15)	Positioned students to engage in certain types of fraction-based reasoning (17)
Focused on distinguishing between an estimated sum and/or an exact sum (9)	Acknowledged how students found exact sums, but then redirected them to estimate (8)
Focused on using estimation as a strategy for determining reasonableness of an exact sum that emerged from a proposed algorithm (6)	Supported students to show their thinking using a written record or representation (10)

Making a Reasonable Estimate

While reflecting on his teaching, the teacher shared that students will need to draw upon their benchmark strategies later in the unit when they are developing algorithms. "I want them to be able to refer back to their estimation strategies so they don't get lost in the algorithms they start inventing". The first task the teacher had the students work on involved determining where a fraction is placed on a number line, and determining how far it is from 0, from ½, and from 1 whole. The second part of the task involved determining if the sum of a pair of numbers is closest to 0, 1, 2, or 3. For each part, students were asked to show work to support their answers. The teacher read the first problem to the class, "On this number line, where does 4/9 belong? Where to you think 4/9 would be if you were estimating? Where would you put it and then why are you doing that?" Student pairs begin to work as the teacher moves from group to group asking questions such as "How far is that from 0?", "What would be half of 9?", "Is that closer to 0, ½, or 1 whole?", "How can you show that?", "How far is 4/9 from 1 whole?" and "What is the 9 [in 4/9] telling you?"

During both small group and whole class discussion there is a strong emphasis on understanding what the numerator of a fraction represents, what the denominator indicates in terms of the numerator and the use of counting, or addition and subtraction, to determine how far a fraction is from 0, ½, or 1 whole. For example, when discussing if 4/9 is closer to 0, ½ or 1 whole, a student came to the front to share where she thought 4/9 was on a number line pre-marked with 0, ½ and 1. When this student placed her mark to the right of the half mark on the number line the teacher asked "Is everyone okay with that?"

Teacher: Is everyone okay with that? Caleb.

Caleb: It would have to be before the half because half of 4/9 would be about point five away from the half mark and so it would be a little way but on the other side [of half].

Teacher: Stephanie do you understand any of that?

Stephanie: Yes.

Teacher: What is half of 9?

Stephanie: 4½.

Teacher: So why don't you help yourself and above the ½ write 4.5 over 9. This would be a good skill to use on all of these problems. So then, the 4/9, would it be before that or after that?

Stephanie: Before.

When the next question in the set is posed (Is 4/9 closer to 0, ½ or 1?) a second student brings up his work. He tried to partition the number line into 9ths but struggled to integrate the marks for ninths with the one-half mark provided on the number line. With some suggestions the class and the student work together to adjust the markings and partition the number line into ninths. One-half is marked as 4.5/9 and 4/9 is marked with a star. They return to the question of how far 4/9 is from 0 and from 1. While some students can easily calculate the distance, counting is encouraged as away to determine how far.

Teacher: How far is 4/9s from 1? Abby?

Abby: 6

Teacher: 6 what?

Abby: 6 ninths?

Teacher: Okay, let's see. Tanner can you start at the star and count over and see if is it 6 ninths?

Tanner counts and gets 5 ninths. This thinking pattern is then prompted for as students work on other problems like this. Some students can do this thinking mentally. Others need to partition a zero-to-one number line or use grid paper to make and mark fraction strips/bars that they can count on. Like Abby, students were prompted to name the unit being quantified—6-ninths rather than 6. Many of the questions and declarative statements posed by the teacher focused on assessing and developing reasoning patterns for determining "how far".

This focus on developing strategies for *determining how far* is critical if students are going to be able to use benchmark reasoning as a tool for later determining if their algorithms are leading to reasonable results. If students do not have a way to determine if a quantity is closer to 0, ½, or 1 whole they will then struggle to determine if the sum of two fractional quantities is closer to 0, 1, 2, or 3. The teacher used numerous problems like this to draw out this type of thinking. The teacher elicited three important estimation ideas: using the denominator to determine how many of a particular fractional unit makes one-half and one whole, representing the fractional names visually on a number line (with full partitioning or renaming 0, ½ and 1 for a particular fractional unit), and counting fractional units to show how far away from 0, ½ or 1 whole a fraction is.

Development of Written Record and Representation

For students with well-developed number sense and computational ability, they were able to efficiently mentally calculate which fractions represented 0, ½ and 1 whole. For example, with 16ths the benchmarks 0/16, 8/16 and 16/16 were easily identified and used. Others struggled. The teacher provided grid paper for students who needed to draw and visualize a fraction bar representing 16ths. Students could mark and count as needed to determine if 9/16 was closer to 0, ½ or 1 whole. Throughout the 3½ days of instruction there were a few instances where students would randomly a guess how far a quantity was from 0, ½ or 1 whole. The teacher would support them to use one of the above strategies without taking over and doing the problem for them. For example, "I don't want you to guess. I want you to [make] a whole fraction strip here. You can cut it up into 8ths." Once the student made the strip, he then assisted him or her to label the representation. Some of his statements included: "Up at the top label it as one [whole]. Under here write how many 8ths that is. Now find where the halfway mark is and label it as ½ above with how many 8ths below." (Etc…). With the fraction strip labeled, he then asked the student, "How far is 5/8 from 0? From ½? From 1 whole?" If the student would guess or struggle to use mental computation, he would then ask them to use the fraction strip representation and count. As larger denominators such as 100ths were introduced, the counting strategy shifted to using subtraction. For example, 26/100 is 24 hundredths (50 - 26 = 24) from ½ or 50/100. So, 26 hundredths is closer to ½. In this teacher's practice there is a clear emphasis on using representations as a tool to give meaning to the quantities that students were being asked to work with. When a student indicated that they thought a fraction was closer to 0, ½ or 1 whole, the teacher would follow by asking why. To support developing and using visual and symbolic representations as reasoning tools, he would say, "So, let's use our strip and see where it does end up." Or "Let's write 50 - 26 = 24 hundredths to show why you think 26/100 is closer to ½".

Students needed similar support when trying to show the reasoning they used when finding an estimated sum for two fractions. On Day 2, after the teacher had observed students working on estimated sum problems, he gave the class a common problem (7/8 + 5/9) to find an estimate for. The students turned in anonymous work that was then displayed and rated. "You guys are going to look at this and rate it on a scale of 3, 2, or 1. Do we think that math is right and do we think that the reasoning they have shown supports their opinion?" The written notation may have been quite simple—"7/8 is about 1 and 5/9 is about ½ so the answer is about 1½". Some students rated this particular response as a 2 because it was important to say for example, that 7/8 is 1/8 from a whole making it is closer to 1 and that 5/9 is close to 4.5/9 or ½. This exercise provided students the opportunity to consider and discuss various expressions of benchmark reasoning.

Benchmark Reasoning, Estimation and Algorithmic Thinking

When students were working to determine if the sum of two fractional quantities was closer to 0, 1, 2 or 3 etc., they were asked to consider if an estimated sum was an overestimate or an underestimate. Using the context of decorating a dollhouse, students knew they had 5 ½ feet of molding to trim two rooms. Needing 3¼ feet for one room and 2 3/8 feet for the other, they were asked to use estimation to consider if 5½ feet of molding would be enough? Some students began to move away from benchmark reasoning toward exact reasoning. Using the *determining* *how far* reasoning, a group of students offered the following, "You know that you have 5 5/8 altogether." When asked how they knew this they explained that "3 plus 2 is 5 and 2 eighths plus 3 eighths is 5 eighths" and "4/8 would be exactly ½."

While this is legitimate reasoning on their part, and will clearly support them when they begin to work on finding exact sums and differences, the focus of the lesson was on estimating. The teacher did not wanted to lose the focus on the thinking patterns for estimating and did not want to discouraging students who could argue using exact equivalent quantities. He used the opportunity to have students consider if their reasoning led to an estimated sum or the exact sum. Students finding exact sums did not always realize they were not estimating. After listening to the reasoning of the student above, the teacher asked,

Teacher: Were you estimating or did you get the exact answer?
Student: We got the exact.
Teacher: Yes, and what were we suppose to be doing in this problem?
Student: Estimating.
Teacher: Yes, we wanted to estimate but I understand that these numbers are pretty compatible…that is good math but we are still gonna keep working on finding an estimate.

This distinction is an important one and will become important later when students are asked to find an estimate to show that their proposed algorithm is leading to a reasonable solution. The use of estimation as a strategy for determining the reasonableness of a sum, as well as what a reasonable sum would be close to, was noted in the discussions the teacher had with students.

In the next problem, a potential exact-sum approach was put on the table for discussion. This problem asked students to use estimation to determine if the solution 12/20 is reasonable for 7/12 plus 5/8. A student offered that 7/12 is 1/12 more than 6/12, or ½, and 5/8 is 1/8 more than ½, so the exact sum has to be more than ½ plus ½ or more than one whole. Here the *how far* reasoning is apparent. Another student, Abby offered that you cannot add the numerators and add the denominators. This is what is implied by the solution 12/20 presented in the problem. However, Abby is not able to say why you cannot do this. The teacher concluded by saying, "We are hoping that your estimate will show that. When you did your estimate, you should have seen that 12/20 is not close to what they real answer should be." Here the teacher positions students to engage in a certain type of reasoning. While Abby struggles to say why, the important point is that estimation can be used as a tool. In this case, the estimate shows that the algorithmic approach of adding numerators and adding denominators does not lead to a reasonable estimate. This reasoning will be important when students start to develop and assess their own algorithms.

Conclusion

These findings build upon the research on teacher practice while developing a content-specific view as suggested by Franke, Kazemi and Battey (2007). The findings highlight aspects of this teacher's local instructional theory for engaging students in fraction operation algorithm development. His practice asks students to engage in reasoning and proof (Ball & Bass, 2003 while developing specific reasoning tools for supporting algorithm development. Representations such as partitioned fraction strips and number lines are tools for *determining how far*. The *determining how far* reasoning is also a tool. Gravemeijer (2004) argues that in a guided-reinvention approach the focus is not teach a set of strategies but to develop a framework of number relations that build a foundation for flexible mental computation. This teacher used questioning and dialogue to help students distinguish between an estimate and an exact answer.

When redirecting students to estimate they were pushed to consider how an estimate can be a tool for determining the credibility of a computational result. This will support them when they design algorithms and work to justify and prove they are mathematically reasonable.

In these results, generic practices such as designing a task or making ideas public (Ball & Bass, 2003) are evident. There is a clear focus on Kazemi and Stipek's (2001) sociomathematical norm that an explanation consists of a mathematical argument, not just a procedural description. By considering these generic practices within the context of fraction algorithmic thinking, specific thinking patterns are made visible for inspection. In this teacher's practice there are purposeful ways in which students were supported so they could make an argument for why they were choosing a particular benchmark. They were encouraged to use models and to develop mathematical symbolism so they could make their benchmark reasoning public and open for inspection. Through this process students were developing language and symbolism to further support their ability to engage in fraction-based algorithmic thinking.

The study examined preservice teachers' (PTs) abilities to pose scenarios that match a division computation with a remainder. The results showed that PTs were able to pose various scenarios but most of them focused on partitive division interpretation. They preferred to leave the remainder as a left over and discarded rather than partitioned as a fraction/percent/decimal, forced to the next whole number, and rounded to an approximate result. More emphasis on providing rich scenario problems during teacher preparation is necessary so PTs will be able to understand the division concept in diverse contexts and deal with remainders accordingly.

Over the past few decades problem posing has gained considerable attention within the mathematics education community gradually familiarizing educators with making aware the benefits of the strategy for improving the teaching and learning of mathematics (Silver, 1994). The National Council of Teachers of Mathematics [NCTM] outlined the importance of problem posing in the *Professional Standards* (1991) document, "students should be given opportunities to formulate problems from given situations and create new problems by modifying the conditions of a given problem" (p. 95). When students formulate problems, they become curious about mathematical ideas and develop deeper understandings of particular concepts (English, 1997, 1998; Silver, 1994). The creation and reformulation of problems within new contexts engages students' thinking and their inquisitiveness in learning mathematics (e.g., Crespo, 2003; Dickerson, 1999; Grundmeier, 2003; Knuth & Peterson, 2003; Leung & Silver; 1997).

Problem posing refers to both the generation or formulation of new problems and the reformulation of given ones (Silver, 1994). Skinner (1991) defined a *problem* as a question engaging someone in searching for a solution. Whereas, Krulik and Rudnick (1982) stated that a *question* required recall, an *exercise* provided routine drills and practices, and a *problem* required careful thought and synthesis of knowledge. These researchers argued that a problem at one time may be an exercise or even a question at some later stage of that individual's mathematical development.

The *Principles and Standards of School Mathematics* (NCTM, 2000) highlights the responsibility of a teacher in choosing and posing worthwhile mathematical tasks to develop and nurture students' understanding of certain concepts. In reality, most mathematical problems come from textbooks as teachers assign them to students. Crespo and Sinclair (2008) argued students of all ages, including those who subsequently become teachers, have limited experience posing their own mathematical problems. Research studies document that many prospective and inservice teachers lack the skills and confidence to go beyond solving a problem (Gonzales, 1994; Silver, Mamona-Downs, Leung, & Kenney, 1996). As problem posing is part of mathematics education reform, teachers must develop skills in formulating mathematical tasks that include appropriate situations to engage students in the classroom (Gonzales, 1994, 1996).

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

Problem posing, especially with division can be a challenge (Silver & Burkett, 1994) as research has shown that many school teachers have difficulties dealing with division of whole numbers involving remainders (e.g., Simon, 1993; Sowder, Philipp, Armstrong, & Schappelle, 1998). For instance, in a two-year long project of the Teaching and Learning Rational Numbers and Quantities Working Group, Sowder et al. noted the confusion of teacher participants when they were presented $37 \div 5 = 7\ R\frac{2}{5}$. The teacher participants believed that 7 remainder 2 and 7 remainder $\frac{2}{5}$ (i.e., $7\ R\frac{2}{5}$) were the same as $7\frac{2}{5}$. During the continued discussion, a facilitator in the project asked them to pose a story problem for which the answer was 7, 8, 2, $7\frac{2}{5}$, 7.4, and 7 remainder 2. When the teachers debated their word problems, they gradually were able to distinguish clearly the contexts when a remainder would be appropriate to consider in each case. Through problem posing, the facilitator helped the teacher participants to realize that 7 remainder $\frac{2}{5}$ was not the correct answer for $37 \div 5$.

In this present study, we explored PTs' capabilities to generate a scenario problem involving division with a remainder. Specifically, we focused on Silver's (1994) formulation of problems emphasizing the creation of a scenario based on a given long division computation with a remainder.

In this study, we explored PTs' capabilities to formulate a scenario problem involving division with a remainder. Also, problem posing was used to assess PTs' understanding of this concept based on the solution of the scenarios they posed. Specifically, we focused on Silver's (1994) formulation of problems emphasizing the creation of a scenario based on a given long division computation with a remainder.

METHOD

The analysis reported in this paper was part of a larger research study examining the problem solving and problem posing skills of PTs. This present study replicated research done by Silver and Burkett (1994) on PTs' conceptual knowledge and contextual connections to division with remainders. Nevertheless, with different perspectives, we attempted to determine the structure of scenario problems individual PTs posed to match a given division computation. The research questions guiding this study were:

a) What kind of scenario problems associated with a division computation and a remainder did PTs pose?
b) What strategies did PTs use to pose scenario problems associated with a division computation and a remainder?

Initially, a pilot study was conducted in Fall 2010 using a group of elementary PTs who volunteered to be part of the project. They completed an open-ended problem posing task as illustrated in Figure 1, adapted from Silver and Burkett (1994). The researchers evaluated response scripts based on a priori coding schemes that emerged from the literature. The results from the pilot study showed that these PTs posed scenario problems that did not match the division computation. The researchers suspected the PTs were not able to understand the written instructions during the administration of the task. Therefore, the instructions for the task were modified to make the task clearer to the participants.

Figure 1. The task adapted with permission from Silver and Burkett (1994).

Subsequently, in Spring 2011, a convenience sampling technique was utilized for data collection. The problem posing task was administered to 33 PTs during the fourth meeting of a 15-week problem solving course. Although the course emphasized Poyla's four-step problem solving process, the professor regularly discussed the importance of problem posing with the PTs during class instructional periods. The participants were working towards their middle grade teaching certification at a southwestern public university in the United States. The majority of the PTs were female (96%), juniors ranging in age from 18 to 22 years old. Each participant completed the problem posing task by writing his/her responses on the answer sheet. They were given 20 minutes to pose multiple scenarios that matched the long division computation and provide different answers to each of the problems posed.

The responses were analyzed by using the classical content analysis that focused on the frequency of each category occurring (Leech & Onwuegbuzie, 2007). The coding was based on Van de Walle, Karp, and Bay-Williams' (2010) description of division of whole numbers. The coding procedure was divided into two phases in order to make the data easier to analyze. In the first phase, a posed-scenario was identified as to whether it matched the long division computation and was categorized into *partition* or *measurement*. Sowder et al. (1998) argued that knowing these two interpretations of division was important when dealing with a context or situation. For example in partition, 540 cookies shared among 40 people, each person has 13 cookies with 20 cookies left over. On the other hand, the situation would be different in measurement when giving 40 cookies from 540 cookies to each one and asked, "*How many people can get 40 cookies each?*" In this case, the units of measure would not be the same -it would be 13 people and 20 cookies left over. Sowder et al. believed that the referent units were the important idea when presenting division within a context. As the task required a context that matched the division computation, the study assessed whether the kind of scenarios PTs posed made sense or were meaningless to the solution they provided. Then, if any posed-scenarios did not satisfy the classification for partition or measurement, they were coded as other including all the responses that used different arithmetic operations such as addition, subtraction, multiplication or combination of operations.

The second phase of the coding procedure dealt with implications of division remainders. According to Carpenter, Fennema, Franke, Levi, and Empson (1999), the context of a problem posed can influence the way the remainder is treated. These remainder effects were categorized as *left over*, *partitioned as a fraction/percent/decimal*, *discarded*, *forced to next whole number*, and *rounded to approximate result* (Van de Walle et al., 2010). Below are examples of responses that were categorized in each type of division remainders:

> *Allison is counting out beads for an art project, in which she needs 540 beads. If she counts the beads by 40s, how many groups will she have?* (Answer: 13 groups and 20 left over, a left over).
>
> *Molly owns a car, which the maximum speed is 40 mph. How much time should she allow to drive 540 miles? (*Answer: $13.50, partitioned as a fraction/decimal).

Jim has 540 ft. of chain. He needs to cut the chain into 40 ft. segments. How many segments of 40 ft. can he make? (Answer: 13 segments, discarded).

There are 540 people waiting to get on a boat. If each boat can carry 40 people, how many boats do you need to carry all of those people? (Answer: 14 boats, forced to next whole number).

Mrs. Jones has 40 students in her class. This year for Christmas, they are making popcorn necklaces to decorate their class tree. If each student gets an equal number of popcorn pieces and Mrs. Jones has 540 to divide up, how many will each student get? (Answer: 13 pieces, rounded to approximate result).

Two researchers coded ten scripts based on the coding procedure (i.e., Phase 1, Phase 2) and achieved 77.1% agreement. Any disagreements were resolved before the first researcher coded the remaining scripts. Then, data were analyzed descriptively (e.g., frequency, proportion) using *Statistical Package for Social Science* (SPSS) version 16.0 (SPSS Inc., 2007) to answer the research questions and the results were presented using tables and charts.

RESULTS

The results were used to portray the structure of scenario problems posed that matched the division computation and to illustrate the strategies PTs used to deal with division remainders in the context they posed. In general, the descriptive statistics from the SPSS results showed PTs were able to generate 170 scenario problems and successfully showed the answers for each scenario they posed. Each of the PTs posed at least three scenarios and 15 PTs generated at most six problems. The analysis of the scenarios is presented in further detail to answer the research questions.

Research Question 1: Kind of Scenario Problems Posed

Most of the PTs (82%) posed a combination of division scenarios associated with measurement and partition. The proportion of the unexpected responses (1.8%) was small as compared to Silver and Burkett (1993). This might be because the PTs were given clear instructions during the administration of the task that they were expected to pose only scenarios associated with division and a remainder. As noted earlier, 170 scenarios were posed in total; however, two of them did not meet the requirements of the task in which the scenarios PTs posed were supposed to match the division computation. In addition, one problem had missing information making it meaningless even though the solution was stated. These are the examples of the unexpected responses:

For every group of 54 oranges in a grocery store there are 40 apples. If this pattern is always consistent, how many oranges would there be if there are only 10 apples? (Proportion problem)

If there are 50 students riding the bus to school and all of them receive a ride, how many buses are needed? (Missing information)

Of the 167 posed problems, 42 were considered redundant because they had similar contexts and repeated the same solution. Specifically, the study demonstrated ten PTs posed at least two similar scenarios without changing the structure of the problem, using the same interpretation of division and remainders. For example, initially one PT posed six scenario problems with correct proposed solutions, but after closely examining the structure of each division problem only two scenarios were considered valid for further analysis. Here are two similar scenarios posed by this participant:

A group of 40 students gathered all of their candy from Halloween. They totaled 540 pieces of candy. If they share equally, how many pieces of candy will each student get? (Answer: 13 pieces of candy)

At a 4th grade party, 540 pieces of pizza were delivered. If there are 40 students at the party, how many pieces will each student get? (Answer: 13 pieces of pizza)

The above examples clearly demonstrate the way this participant interpreted the meaning of division using partition. Even though this PT posed six problems, she/he was not able to generate any scenario associated with division that related to measurement showing this PT had difficulty seeing division in this dimension. In fact, only 89 (47%) of the scenarios that PTs posed were focused on measurement as illustrated in the following:

A convention center must prepare their showroom for the TMTA Piano Convention. To maximize the number of vendor booths, 40 tables can fit in one row across the room. If there are 540 tables, how many rows of 40 tables can you create and how many tables are left over? (Answer: 13 rows and 20 tables)

Timmy has 540 chickens. He needs to determine how many chicken coops he should buy. Each chicken coop can hold 40 chickens. How many will he buy? (Answer: 14 coops).

On the other hand, the majority (53%) of the problems posed were based on partition interpretations in which the results were similar to Silver and Burkett (1994). In fact, five of 33 PTs posed only scenarios associated with partitive and one participant focused solely on measurement. This study showed that PTs were able to pose reasonable scenarios and correct answers with an appropriate referent unit (e.g., 13 rows and 20 tables, 13 pieces of candy, 14 coops) in each case. It seemed that most of PTs were able to understand the relationship among the dividend, divisor, quotient, and remainder. In addition, the study also found two PTs posed contexts by interchanging the divisor and quotient of the original computation. One participant consistently posed two scenarios that used 540/13 to illustrate the meaning of division using measurement and partition.

The World Eating Championships are being held in Los Angles this year and is sponsored by McDonalds. McDonalds decides to give 540 Big Macs for the competition. If the average competitive eater can eat 13 Big Macs, how many people should they hosted to ensure they do not run out of Big Macs? (Answer: 41)

EA Sports is hosting an Online FIFA "Goalathon". A "Goalathon" is a rare for all FIFA players to reach 540 soccer goals in 13 weeks. How many goals must a player average a week to reach 540 goals in 13 weeks?Round number to two decimal points (Answer: 41.65).

Based on the responses, this participant was aware that the proposed answers would be different as he/she interchanged the values that showed his/her understanding of division problems. Also, similar to Silver and Burkett's study, the results showed that PTs posed a number of 'Yes/No' scenario problems (6.5%), for example as following:

There are 40 people at a conference that need to be fed equally. The chef makes 540 cookies that can be eaten. Each of the 40 people must eat the same amount of cookies and cannot eat half of a cookie. Will there be any leftover?

Even though this problem was associated with the partition interpretation, the researchers believed it was not challenging and did not engage students' thinking as it could be answered simply by stating yes or no. It did not fit with the definition of a *problem* as defined by Krulik and Rudnick (1982). Also, most of the PTs were able to provide an appropriate solution for the scenario they posed and considered the effect of remainders on the answers. More detailed discussion on remainders and answers for the posed problems that were provided by PTs are presented in the following section.

Research Question 2: Strategies with Division Remainders

Part of the requirement of the problem posing task was to provide different answers, so the researchers examined each of them in depth as they were related to how remainders were handled. The results provided a source of information about PTs' understanding of division involving remainders that can be categorized as a left over, partitioned as a fraction/decimal/percent, discarded, forced to next whole number, and rounded to approximate result (Van de Walle et al., 2010). Of the 167 responses, 42 were eliminated because they had similar contexts and repeated the same solution. In addition, six were dropped because of incorrect proposed solution. Therefore, the analysis of division remainders was based on 119 valid responses. As displayed in Figure 2, the researchers found PTs preferred to leave the division remainders in form of a left over in which 35% of the scenarios were in this category. The category of division remainders used least by the participants was the forced to next whole number in which only 14 (12%) scenarios were coded for this category.

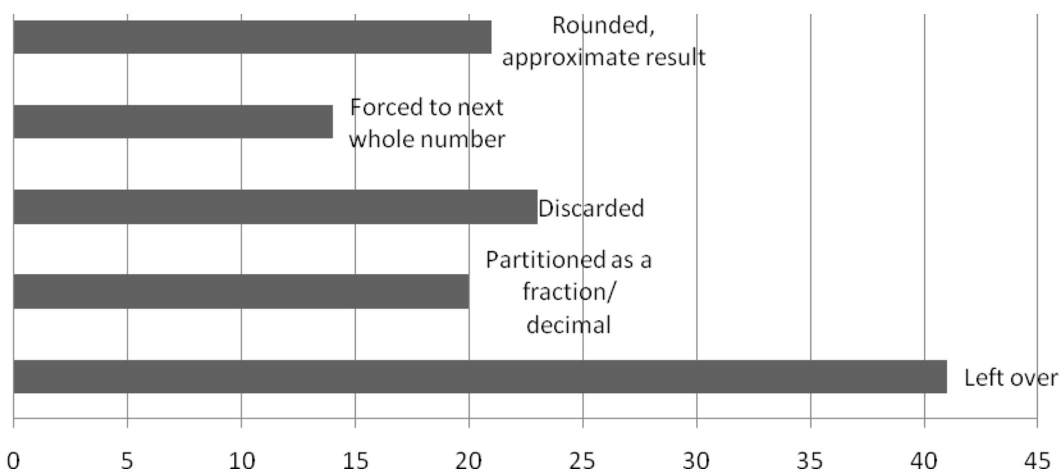

Figure 2. The analysis of division remainders

In addition, 11% of the scenarios (13 of 119 responses) were noted as errors because they provided unreasonable answers that did not match the remaining context of the posed problems. For instance, '*There are 540 children going to camp and 40 buses to get them there. How many children will be on each bus?*' The answer given was 13 children, which was not realistic that showing the remaining 20 children were ignored and making the problem meaningless and not practical. The scenario clearly stated '*There are 540 children going to camp*', which meant all children were supposed to go to the camp. Based on this context, these 20 children should be together with other children on the buses so the appropriate answer would be about 14 children as it forced the figure to next the whole number. Two PTs made a 'silly' error by mistakenly writing 13.2 instead of 13.5 as a solution and three PTs gave incorrect answers to the posed scenarios.

Discussion

The study reveals that the selected PTs were able to show their understanding of division with remainders. In regard to the first research question, the researchers found from the structure of the scenarios posed that PTs were more comfortable with sharing scenarios (partition) compared to the equal size groups (measurement). The selected PTs were able to pose reasonable scenarios and to provide correct answers with an appropriate referent unit (e.g., 13 rows and 20 tables, 13 pieces of candy, 14 coops) in each case. It seemed that most of PTs were able to understand the relationship among the dividend, divisor, quotient and remainder.

In regard to the second research question, even though they were able to put the division computation in a context, they could not deal with the remainder accordingly. They were not able to think of the remainders as fractions or as rounding-up, rounding-down the results depending on the context they posed. Specifically, most of PTs preferred to deal with division remainders in form of a left over and discarded. When PTs discarded the remainders, most of the problems were thus meaningless and not practical.

Teacher educators should place more emphasis on providing rich scenario problems during instruction so that PTs can see the different meanings of division clearly and be able to understand these concepts profoundly. In addition, teacher educators should encourage PTs to deal with a remainder instead of just leaving it as a left over or discarding the remainder. Much more remains to be understood about PTs' abilities with problem posing and their understanding of division; therefore future investigation is necessary to explore the benefit of using of problem posing in discovering PTs knowledge and understanding of a particular mathematical concept.

THE POWER OF INVENTING PERSONAL REPRESENTATIONS: A CASE STUDY OF DAVID

Suzanna Schmeelk
Rutgers University
sschm@rci.rutgers.edu

Carolyn Maher
Rutgers University
carolyn.maher@gse.rutgers.edu

This study describes how nine-year old David, in exploring the ordering of fractions on a number line, illustrates his understanding of fraction ideas by offering multiple representations of his solutions. David begins his problem solving by building a physical model with Cuisenaire rods. He then justifies his solution to the class using verbal explanations accompanied by gestures, drawings and symbols.

Introduction

Fractions are too often introduced in schools using standard symbols and notations that do not carry meaning for students. For decades, researchers have documented the shortcomings of traditional instruction that focus on rules and algorithms for the learning of fractions and their operations (Erlwanger, 1973; Freudenthal, 1983; Maher, Davis and Alston, 1993; Steencken and Maher, 2002; Streefland, 1991). Studies have shown that learning mathematics, when using and linking various forms of representations, can promote inquiry and higher levels of thinking (Ball and Bass, 2003; Even, 1998; Richardson, Berenson, Staley, 2009). The process by which students build their own understanding is complex process and involves building personal, meaningful mental representations that can take on many forms (Davis, 1984; Goldin, 1998, 2003; Goldin and Janvier 1998). Students can then use their personal representations to express their understanding. In this paper, we explore the variety of personal representations used by David to express his understanding of number concepts. In particular, we investigate: "What representations does David use to express his understanding of fraction as number?"

Theoretical Framework

The view that learning should be meaningful is not new. Decades ago, Dewey (1938) stressed the importance of learning by doing. Today, mathematics educators emphasize the importance of building meaning in the learning of mathematics, citing the importance of student engagement in thoughtful problem solving s context for new learning (Maher, 2010; Maher, Powell, & Uptegrove, 2010). According to Davis (1984) and Davis and Maher (1997), the process of making sense of a problematic situation calls for the restructuring of knowledge. Previous experiences that learners bring to a problem-solving exploration can serve as assimilation paradigms for new learning. As learners examine and compare earlier experiences, they either solve the new problem or restructure their existing knowledge to accommodate the new conditions of the new problem. Making use of personal representations is key in the process. The variety of personal representations that a learner can bring to a problem-solving activity makes the understanding richer and, ultimately, more durable, in that the ideas can be related and restructured as needed. Recent studies have documented the durability of learning when it is built in a meaningful way (Aboelnaga, 2011; Ahluwalia, 2011; Sran, 2010; Steffero, 2010, Schmeelk, 2010). These studies show that students build on and extend their knowledge when supported by conditions that support collaboration with appropriately designed tasks. Also, they demonstrate the durability of learning over time. Representations are key in that learning. According to Goldin and Janvier (1998), representations can be interpreted in the context of external physical situations, linguistic embodiments, formal mathematical constructs and individual's internal cognitive configuration. The PME working group on representations has developed extensive discussions on various representation forms, and from these discussions, there has arisen an understanding that in analyzing the various representations, there is a need to understand mathematical notations, branches, recordings, individual productions, external situations, as well as individual mathematical learning and understanding (Goldin 1998). Translation between and among multiple representations is individual, varied and independent (Superfine, Canty and Marshall, 2009; Kaput, 1998). As a result, individual, personal representations that student's use to invent are more powerful than those that are imposed (Vergnaud, 1998). It is our view that students need to develop their understanding of mathematical ideas using the schemes and representations that are personal. Access to manipulatives, useful as tools to illustrate external representations, can assist the development of student internal representation schemas. According to Gattegno (1961, 1963), using Cuisenaire rods can foster student understanding of fractions. He suggests a multi-stage introduction to Cuisenaire rods, including (1) free play and (2) free play that is accompanied with directed activities with the rods, in which discussions and observations for the rod relationships are informally discussed. Then, what might follow is more free play accompanied with directed activities with the rods, in which formal notation is introduced without directly assigning number values to rods. Finally, free play accompanied with directed activities, in which the formal notation is extended with directly assigning number values to the rods, might follow. Components of the framework proposed by Gategno were integrated into this research in students' investigation of fraction ideas with Cuisenaire rods available as a tool.

Study Context

This research took place in a fourth-grade rural/suburban classroom consisting of 25 heterogeneously grouped nine and ten year old students. In this school's mathematics curriculum, fractions and operations were not introduced until the following year. It was important for the researchers to study how the students made sense of the fraction/rational number ideas though their problem solving and sharing of ideas before fractions were formally introduced as part of their fifth-grade mathematics curriculum.

Data and Methodology

The data were collected from multiple sources. All sessions were videotaped with multiple cameras during extended classroom sessions that lasted from fifty to seventy-five minutes. The video data and their full transcripts, along with student work and researcher observation notes, were used to triangulate data. Student work consisted of personal written inscriptions and collaborative overhead inscriptions. The video data have been digitized and are stored, along with transcripts, in a repository as a component of the Video Mosaic Collaborative (see http://videomosaic.org).

Background

Twelve sessions transpired before the focus sessions that are described in this report. During the earlier sessions, students explored fraction as number, fraction as operator, equivalence, ordering and fraction comparison ideas. The student reasoning in the form of conjectures and argument strategies is described by Reynolds (2005). Detailed reasoning forms used by the students, including upper and lower bounds, cases, contradiction and recursive were analyzed by

Yankelewitz (2009) and Yankelewitz, Muller and Maher (2010). The first seven sessions were analyzed for students transitioning from an understanding of fraction as operator to fraction as number (Steencken, 2001; Steencken and Maher, 1998; 2003). In these studies, the students' verbal and inscription representations were examined in detail for how they built their understandings. All of the studies reported that the students' verbal expiations became increasingly more precise over time.

Results

For this report, we describe three episodes that provide as examples of the variety of representations that David used to express his growing understanding of rational number ideas. For more detail and full transcripts, see Schmeelk, 2010. Video clips can be viewed on the Video Mosaic website: http://videomosaic.org/.

Episode 1: 11-01-1993

In this episode, David was working on the problem: "Which numbers are bigger and smaller—1/2, 1/3, 1/4, 1/5?" After building rod moles with his partner, he offered a solution to the class and used gestures to represent an imaginary number line. He demonstrated (see Figure 1) four fractions—one half, one third, one fourth and one fifth—are larger. The clip exemplifies his awareness of the partitioning of a unit interval into regions representing the fraction parts.

Line	Speaker	Transcription
78	Researcher	[Writes one half, one third, one fourth and one fifth on over head] So, if I were to say things, like one half, one third, one fourth, one fifth, right? If I were talking about these numbers then would you know which are bigger and which are smaller? How many think you know which are bigger and which are smaller? Who could explain why?
79	Class	[Many students raise their hands.]
80	Researcher	David, what do you think?
81	David	If you have one half cuts right there. [motions ½ on an imaginary unit] If you have one third it cuts right there [motions to where one third would cut on a unit] You would have three pieces.

Figure 1. David gestures as he orders fractions on a number line

The researcher then asked David to use the overhead projector to explain his ideas. David, made drawings of rod models and, again, justified his ordering of fractions (see Figure 2). At the overhead projector, he drew rod pictures to show the magnitude of the five fractions with respect to a unit rod that he labeled whole.

Line	Speaker	Transcription
82	Researcher	You want to come draw that for me? You all hear what David is saying?
83	David	[Walks up to OHP in front of room.]
84	Researcher	Want to draw your one. Call something one and zero?
85	David	Maybe the orange
86	Researcher	Just sketch it …
87	David	If this is the one here
88	David	… then one half would be there …
89	Researcher	Can you mark one half right where you put it, like put it right underneath so we can see it?
90	David	What do you mean?
91	Researcher	Just write the number one half where you want to show one half.
92	David	Then, one third
93	David	Then, one fourth
94	Researcher	Then, one fifth. Thank you very much.

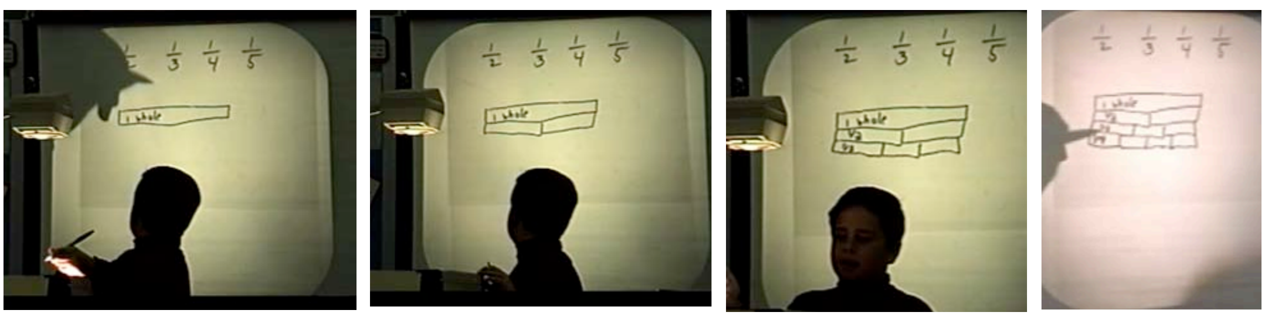

Figure 2. Images of David ordering fractions on the overhead projector

Episode 2: 11-03-1993

In this episode, the researcher summarized an earlier discussion about how the numbers on the number line continue. The researcher then asked the students to review their assignment, which was to think about the numbers between two whole numbers. David responded with a metaphor of a microscope, suggesting how a microscope could show the space between numbers, indicating that an observer would see multiple numbers through magnification.

Line	Speaker	Transcription
208	David	I think that you really can't see it to well. But, if you use a microscope, then you are seeing closer and it looks like you are seeing more; but,

		you're really not—you're just looking closer than before.
235	David	I think that you can take the little smallest thing and, then, put it under a microscope; and, you will have a lot more space. But, you really don't. It looks like a lot more space; but, it really isn't. You are just magnifying it.

Later in the episode, the class was asked to investigate on where the number one one-hundredth might be placed on a number line. David used a ruler to place the number one one-hundredth on his number line model at his desk (see Figure 3).

Line	Speaker	Transcription
251	David	On my paper, I had a ruler, that I was using, put up to [the number line]. It think it was a millimeter or something. I had a ten inch number line, so I put [the number one one-hundredth,
252	Researcher	So that is how you placed one one-hundredth
253	David	Yeah

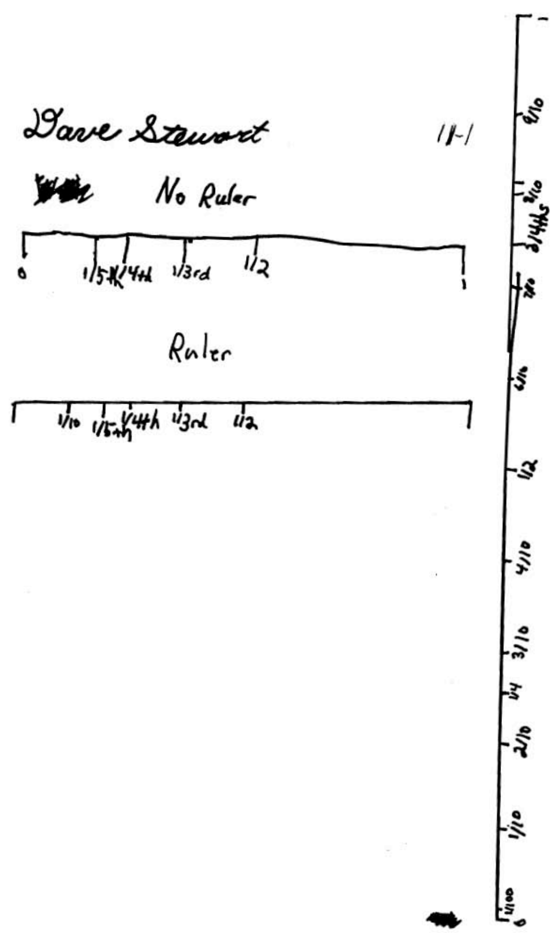

Figure 3. David's sketches for the placement of one one-hundredth on a ruler

Episode 3: 11-12-1993

In this episode the researcher extended the bottom of the model to represent a number line and asked David to place the fractions. David responded by correctly labeling the number zero, one fourth, one half, three fourths and one. Under the number named one half, David also placed the number two fourths. The clip (see Figure 4) showed that David used Cuisenaire rods as an assimilation paradigm to assimilate he transitions from fraction as operator using rod models to fraction as number in placing the numbers on the number line, noting the equivalence of one half and two fourths.

Line	Speaker	Transcription
111	David	Four fourths equals one whole. Two halves equals one whole. And, two fourths equals one half because one half is half of one whole. So, two fourths is one half.
169-173	David	I just drew it like that because that's the one whole [gestures to top level]. These are the one fourths [gestured to the second level]. And, that's the half [gestures to the bottom level]. This would be zero [gestures to the left most vertical line] and that would be one [gestures to the right most vertical line].
174	Researcher	Let me ask you to something here that might help me. I want theses to be here [draws in lines to turn the rods into a number line]. Can you place your numbers, here, now?
175	David	You mean like one half?
176	Researcher	Where's zero?
177	David	[Draws in zero, one fourth, two fourths, one half, three fourths and one].

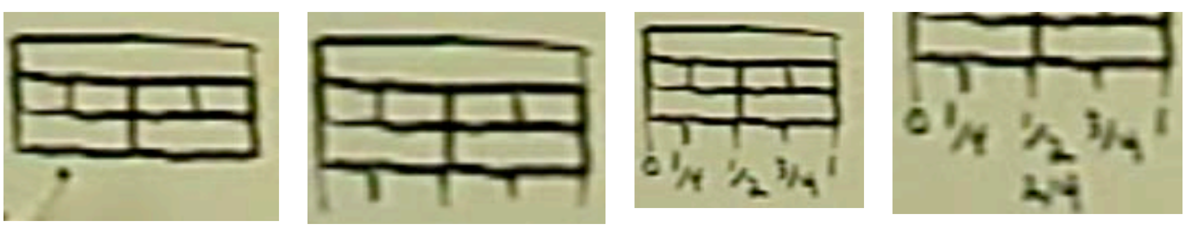

Figure 4. David's diagram showing the placement of two fourths

Conclusions and Implications

David's rod model became a useful representation for transitioning to the placement of fractions on a number line. In episode one, David used gestures in explaining his rod model and drew diagrams of rod models justify his fraction placements. In the second episode, David used external microscope representations to convey his understanding of density. Later, in the same episode, he accurately places the number one one-hundredth on a number line using a ruler. In the final episode, he accurately conjectures that one half is equivalent to two fourths, indicating some understanding of fraction equivalence, using model drawings to justify his conjecture. David was developing and expressing his awareness of the idea of the density of fractions, using a metaphor of a microscope to indicate that there is more space between two numbers on a line for the placement of other numbers. David's exploration of fraction ideas shows that he is able to coordinate the ideas of fraction as operator and fraction as number, an important foundation for growth in fraction knowledge. Exploration and free play, accompanied by opportunities to be engaged in thoughtful problem solving are important components for building meaning of mathematical ideas. David's problem solving activity was thoughtful and productive and shows successful transitioning of a variety of representations.

Endnotes

1. The research was directed by Carolyn A. Maher. It was funded in part by grant MDR 9053597 from the National Science Foundation and by grant 93-992022-8001 from the NJ Department of Higher Education, directed by Robert B. Davis and Carolyn A. Maher. Any opinions, findings, conclusions or recommendations expressed in this work are those of the authors and do not necessarily reflect the views of the National Science Foundation or the NJ Department of Higher Education.

DEVELOPING FRACTION NUMBER SENSE WITH PRIMARY LEVEL PUPILS

Armando Sepúlveda

ivonne.regules@ijm.edu.mx

This article describes the experience resulting from applying the Rational Number Project (RNP) sequence of activities with a group of 6th grade pupils which consists of working with concrete material at all times and making constant reference to the other representations. The reasoning expressed by the students gives a clear idea of the benefits they obtained with this approach, since they were able to transfer their knowledge to new situations. Additionally, it was shown that the use of concrete materials is not a waste of time, contrary to what many primary teachers argue, since there was enough time to cover the contents with encouraging results.

Some studies (Cramer, K., Behr, M., Post, T., Lesh, R., 1997; Cramer, K., Henry, A., 2002; Huinker, 2002) suggest that in order to learn and understand fractions young children require: to experience handling a variety of concrete materials; to communicate their mathematical ideas through oral expressions, pictures and symbolic representations; to solve real life problems; to be given the opportunity to express and share their mathematical ideas with teachers and peers; as well as to be involved in a teaching environment that emphasizes the understanding of concepts before formal symbolic and algorithmic work is introduced. This article analyzes the experiences resulting from a Fractions Workshop, in which the lessons suggested by the Rational Number Project (Cramer, K., Behr, M., Post, T., Lesh, R., 1997) were applied. The general aim of the Workshop was to help the participants develop a deep understanding of the concept of a fraction.

Some of the questions guiding the study were: How can we help students acquire correct ideas about fractions? How can we help pupils feel confident about their mathematical abilities? Which teaching sequences bring about a better understanding of the concept of fractions, of fraction equivalence, of the relationships between the different modes of representation, and their relevance in real life situations?

Conceptual Framework

There's a general concern amongst mathematics teachers of different levels with respect to the way students learn fractions. Most educators agree that there has to be a change in the way fractions are taught, but there is no consensus as to how to carry out such change.

Several authors have made interesting attempts at broaching this subject; for example, Behr (1992) suggests that in the initial stages of introducing fractions the teacher should present situations such that pupils are faced with the possibility of constructing their own qualitative concept of order, equivalence and size of fractions. Likewise, due to the complexity of the concept of fraction and the variety of situations to which fractions apply, it's important to focus on the development of a quantitative understanding which can be achieved by using concrete models and emphasizing meaning instead of procedures (Bezuk, 1989). It is also necessary to present children with relevant situations which will allow them to make connections between their academic work and real life contexts, and between the different representations (Scaptura, 2007). In this sense, Lesh (Cramer, K., Behr, M., Post, T., Lesh, R., 1997) suggests that children learn fractions when they have the opportunity to explore ideas and make connections between

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

the different modes of representation. Lesh put forward the translation model shown in Figure 1 as a way to represent how fraction mathematical ideas are related. This diagram was used as a model for the development of the Rational Number Project (RNP) curriculum.

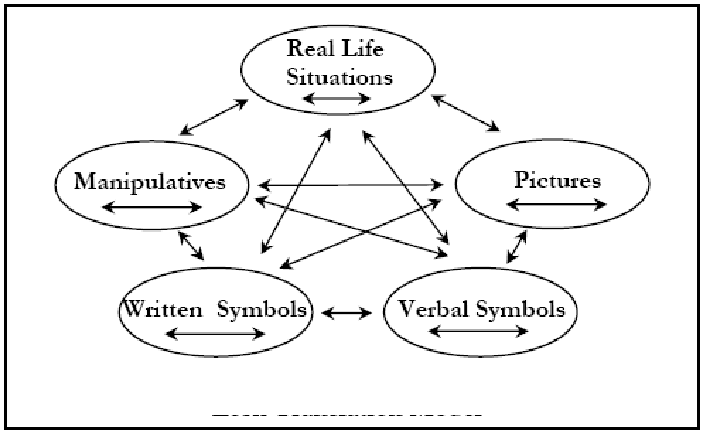

Figure 1. Lesh Translation Model

RNP Curriculum

The RNP curriculum suggests a sequence, alternative to that which is traditionally presented in primary text books. It bases its philosophy on the principle that it is necessary for the child to use concrete materials in order to: be able to understand and feel confident with the different fraction modes of representation; perceive them as part of a whole, as part of a collection of objects, or as a division; acquire a solid understanding of fraction order and equivalence; all this as a foundation necessary for meaningful work with fraction operations. With respect to the teaching of fractions, the National Council of Teachers of Mathematics (NCTM) establishes as aims: the development of number sense, the use of a variety of concrete models for representing fractions, the application of the teaching of fractions in context and to develop the ability to make connections between the different modes of representation (NCTM, 2000). The RNP curriculum strives to achieve such aims (Behr, 1992).

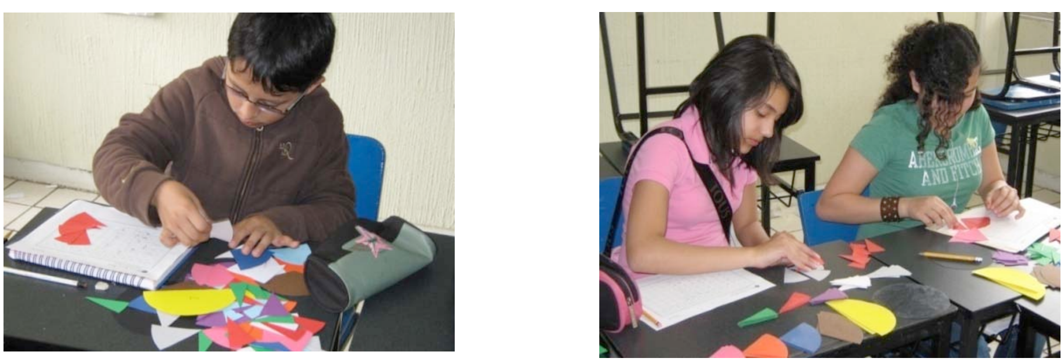

Figure 2. Working with concrete materials.

Participants, Method of Investigation, Procedures

The aim of this study is to carry out a qualitative analysis of the results obtained through working with some of the activities suggested by the RNP Level 1, during a workshop organized in a private school in the State of Michoacan, Mexico, with a group of 6th grade students (12

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

year-olds). In order to select the 15 pupils who would receive most benefit from such work, a diagnostic test was applied to a group of 60 students; those who appeared to have greater difficulties regarding the topic of fractions were invited to participate. Whilst the Workshop was offered as a voluntary activity, the pupils made a commitment to participate throughout the sessions. The Workshop consisted of thirty hourly sessions, which took place three times a week during the afternoon. The material used was that which the RNP suggests: coloured circles divided in sections of different sizes, paper strips for folding, and chips to be used as discrete material. The aim of the Workshop was to help students develop number sense of fractions by: understanding the concept of flexibility of the unit, understanding and using fraction equivalence, ordering and comparing fractions using different strategies, adding and subtracting fractions.

Results

Diagnostic Exam

This exam consisted of twenty questions, designed to discover the performance level of the pupils with respect to: shading part of a whole -in discrete as well as continuous quantities-, locating fractions on a number line, reducing fractions, finding equivalences between common and decimal fractions, adding and subtracting fractions with the same and different denominator. Some aspects worthy of mentioning regarding the results of the diagnostic exam were that: most pupils were able to divide a figure in equal parts and shade a given part, but they found it difficult to shade a set of objects (see Figure 3). This could indicate that during their school years they have had more experiences using continuous rather than discrete quantities. In relation to the operations, most of the group managed addition and subtraction of fractions with like denominators, but were not able to do the operations with unlike denominators. This could lead us to think that the pupils had a poor number sense of fractions.

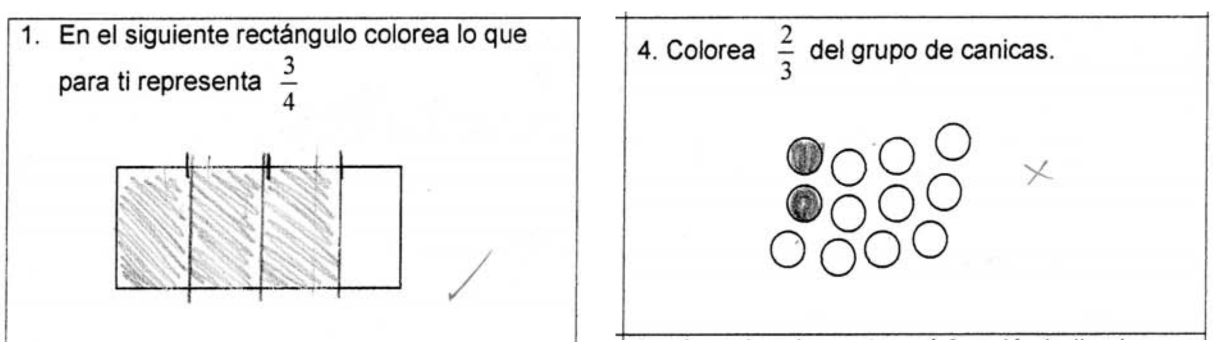

Figure 3. Daniela's work in the Diagnostic Exam.

Experiences during the Workshop

The whole teaching sequence was based on the RNP, making adjustments in time only: the material for 20 lessons was covered during 30 Workshop lessons. During the first session of the Workshop the pupils were given their circles for them to cut out, in order for them to become familiar with the colors. The pieces were stored in an envelope and were used throughout the sessions. The methodology used consisted of reviewing the topics of the previous session, covering new material and closing the session with reflections and comments from the pupils. Basically the sessions were teacher-guided, with brainstorming and individual participations and, sporadically, pair work. The participants had a notebook where they registered their work as well as the ideas they came up with. Some worksheets, included in the RNP, were also used.

The last two sessions of the Workshop were devoted to evaluation: a written, individual summative evaluation, to determine whether the aims had been reached; and an oral, group, formative evaluation designed to discover the pupils' opinion regarding their perception of the Workshop as well as to give them the opportunity to suggest ideas of how to improve it.

From the beginning, the students were very enthusiastic in participating; their informal comments reflected that the topic of fractions caused them anguish and were very interested in improving their understanding of the same. Whilst they cut out their circles they shared some of their discoveries: "the greater the denominator, the smaller is the piece"; also, when they put some pieces on top of other pieces they discovered that not all of them have equivalences (for example that eights and fifteenths only coincide in the unit).

During the sessions devoted to working the concept of flexibility of unit, i.e. using different pieces as the unit, the pupils reached the conclusion that the whole doesn't have to be a complete circle (see Figure 4); also that the number of pieces that fit in a larger piece constitute the denominator. In words of a participant:

Miri: So, if the red piece fits 5 times in the brown piece then you can say that red is 1/5 of the brown.

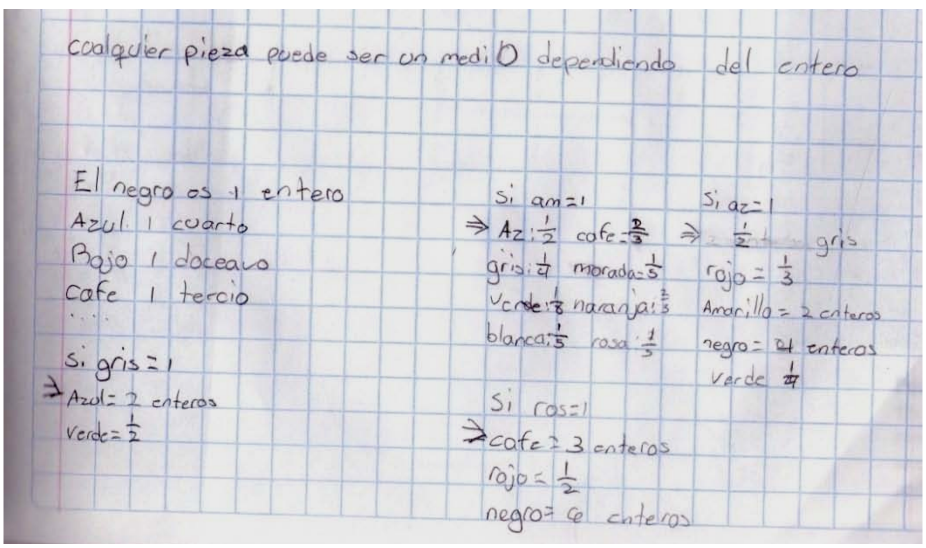

Figure 4. Aitana's work on the flexibility of the unit.

Equivalences came to them naturally. In previous explorations with their material they had come to the conclusion that there are pieces that take up the same space as others. The work started with fractions representing ½ , and afterwards moved on to other equivalences. When they compared the use of concrete materials with the written symbols they quickly realized that if one multiplies numerator and denominator by two, one obtains a number which represents the same fraction but is divided into a different amount of parts. They soon made a generalization: given a fraction, if you multiply numerator and denominator by the same amount you obtain an equivalent fraction:

Ricky: It is by 4 above and below. That is, the one above and the one below will always be the same. [If you multiply above and below by the same amount you get an equivalent fraction.]

Thus, the children were able to infer an idea that is generally used as a formula in traditional instruction: to obtain an equivalent fraction you have to multiply numerator and denominator by the same number.

In the sessions that addressed fraction comparison, the pupils used different strategies. Some made drawings; others made use of the transitive property of numbers:

Monse: ¾ > ½ because since 2/4 = ½ then 3/4 has to be larger.

Others used the idea of the unit:

S. Paz: you look at the number on top and check how much it needs to complete a unit. If there's more than one half missing then the fraction is smaller than 1/2.

These inferences show that they were starting to apply their knowledge of equivalent fractions (1/2 = 2/4), and that they had a clear idea that the denominator indicates the number of parts into which the unit is divided.

Afterwards, the topic of fraction addition was broached, starting by making estimations and deciding whether the answer was smaller or larger than ½ or of the unit. Some pupils felt safer with the concrete material and gave the answers using their circles. Others showed very interesting strategies, for example:

Sagar: I'm going to add 1/8 + 9/10, since 9/10 needs 1/10 to become a unit and 1/8 > 1/10 then the sum will be greater than 1.

Also:

Aitana: If I want to add1/3 + 3/4, 3/4 needs 1/4 to become a unit, since 1/3 > 1/4 then the sum will be > 1. As for 1/3 + 2/6, I can see that they are equivalent, then the sum will be 4/6; since 1/2 = 3/6 then 4/6 > 1/2.

Still other participants used the notion of equivalent fractions and gave exact answers, ignoring the instruction of trying to find a close estimate.

This is the extent of the material covered during the Workshop because, even though the initial objective was to reinforce addition and subtraction of fractions, a time limit of 30 sessions had been established, as was mentioned afore.

Once the Workshop concluded, three pupils were interviewed; these interviews were recorded and transcribed. It's important to point out that the problems broached during the Workshop were different to the ones described herein. The following situations were among some of the most outstanding contributions. (I = Interviewer).

I: [Solve the following problem]. Marco and Memo each have a packet of M&M's, with each packet having the same amount of candies. Marco ate 2/3 of his packet and Memo ate 3/4 of his. Can you tell me whether they ate the same amount or one of them ate more candies than the other? Explain why.

Aitana: Memo ate more because let's say he divided his M&M's into 4 groups and ate 3 of those groups then he was left with a small group, whereas Marco divided his into three groups and ate two of those and was left with a larger group, therefore he has more M&M's left than Marco.

[…]

I: OK, now we are going to use these cubes. Thomas made a tower of cubes. He used 6 cubes to make 1/5 of the tower. Can you tell me how tall the tower was?

Aitana: How tall was the tower?
I: That's exactly what I want you to tell me.
Aitana: Right, so how tall was the tower? Let's see, it must have been 30 cubes tall because if I divide 30 into 5 equal parts I get 6 and if I choose one of those [groups] then I chose 1/5 of the tower.
I: OK, now how about this problem: Thomas made another tower using 8 cubes, which represent 2/3 of the whole tower. Can you tell me how tall the tower was?
Aitana: The tower measured 12 [cubes], because if you are telling me that 8 cubes represent 2/3 [of the tower] then one third has to be 4 [cubes] because I understand there are 3 groups.

It is evident that this pupil has a clear idea of the concept of a fraction since she was able to give logical explanations when solving situations that were unknown to her.

During the last session, where the participants were asked to evaluate the Workshop, they commented that they considered too much time was wasted in forming their circles at the beginning of each session, thus diminishing the amount of time of significant work. They also suggested that they would have liked more games related to real life situations. As a reply to this suggestion it could be interesting to add to the Workshop some baking sessions which would give the pupils some practice with using fractions in real life situations.

After carrying out a general analysis of the sessions, it is deemed important to promote teamwork (Hagelgans, 1995), as well as to encourage written communication of their mathematical ideas through the use of a mathematics journal (NCTM, 2000).

Final Comments

At the time of implementing the activities it became evident that the pupils found it difficult to move away from traditional learning, which privileges procedural learning of mathematics as opposed to trying to make sense of the conceptual ideas. Though the diagnostic exam made it clear that they had a poor comprehension of fractions, their procedural knowledge gave them a sense of false security.

Throughout the 30 sessions of the Workshop most of the pupils showed progress in their comprehension of the meaning of fractions, equivalences between fractions, ordering strategies, and translations between the different modes of representation. It was interesting to notice that in different situations: the pupils used their own explanations, they "invented" their own method of solving the different activities instead of depending on the algorithms they had learned, they were capable of explaining their reasoning to their peers, and they had the ability to solve problems which were new to them. All in all, they trusted their reasoning instead of asking for explanations or solutions. Nevertheless, even though some pupils achieved good results and felt safe using their concrete models, not all of the participants were able to make the translation to the symbolic representation. The issue of whether increasing the number of sessions would help these pupils achieve this matter still remains an uncertainty. Another question that remains unresolved is if teachers were to implement these strategies from the moment the pupils first come in formal contact with fractions (in the third grade of primary school), would their pupils be able to understand them better.

It is not easy to quantify the learning that took place in this group of pupils. Only time will evidence if the experience they lived was significant in their construction of the concept of fractions. An undeniable fact is that the experience started with a group of pupils with many doubts about their mathematical abilities, who felt uneasy about participating, and unable to answer most of the exercises of a fractions exam. The end result of the 30 sessions was to have a group of more confident pupils who were happy to have participated in the experience, and possessing the knowledge that fractions are a topic far easier than they had imagined and with the certainty that if they don't know how to solve a problem they can ask without feeling afraid of being judged. These facts are well worth the time invested in the Workshop.

PROSPECTIVE ELEMENTARY TEACHERS' DEVELOPMENT OF FRACTION NUMBER SENSE

Juliana Utley
Oklahoma State University
juliana.utley@okstate.edu

Stacy Reeder
University of Oklahoma
reeder@ou.edu

Can elementary teacher candidates "unlearn" harmful algorithms used with fractions as they are invited to develop fraction number sense? This study examines the development of prospective elementary teachers' fraction number sense during an intermediate (grades 5-8) mathematics methods course. During this course, participants were involved in a variety of activities and tasks used for the development of fraction number sense.

Number sense "represent[s] a certain way of thinking rather than a body of knowledge that can be transmitted to others" (Sowder, 1992, p.3). In order for teachers to create opportunities and experiences for students to develop meaningful understandings of fractions, teachers not only need to have a well developed and meaningful understanding of fractions themselves but also pedagogic practices that provide experiences for students to explore and construct ideas about fractions. This research is based on the premise that prospective teachers bring with them to their methods courses a somewhat limited understanding of fractions and that a methods course taught from a constructivist orientation may change and extend that understanding. Thus, the purpose of this study was to explore changes in prospective elementary teachers' fraction sense. The specific research question was: Can carefully selected experiences in a mathematics method course designed for elementary education majors affect their fraction sense?

Theoretical Framework

According to Schneider & Thompson (2000), number sense includes a solid understanding of the meaning of numbers and numerical relationships; flexible thinking about numbers (e.g. can see ten in a variety of ways). Based on these descriptions of number sense, researchers in this study define fraction sense as an intuitive feel for fractions and fraction relationships; flexible thinking about fractions (e.g. can use benchmark fractions to determine reasonableness of fraction operations).

There have been many calls for change in fraction instruction to move from procedural instruction to helping students develop conceptual understanding (Lamon, 2005; National Council of Teachers of Mathematics, 1989, 2000; Van de Walle, 2007). Deborah Ball posed the following question for mathematics educators in a paper presented at the eighth annual meeting of PMENA posed the following important questions for mathematics educators:

- What is taught in different mathematics methods courses and what do prospective teachers learn?
- What goes on in the mathematics courses that teachers take at the college level and how do these experiences fit with students prior experiences in mathematics?
- How can teacher educators productively challenge, change, extend what teacher education students bring?

PME-NA 2011 Proceedings

Methodology

Participants were 42 female (2 non-traditional) prospective elementary teachers enrolled in an intermediate mathematics methods course. This course is a part of their last year of coursework and focuses on teaching mathematics in grades 5-8. All participants had completed twelve credit hours in mathematics including a course designed specifically for elementary education majors that addresses the foundations of numbers (set theory, numeration, and the real number system), number theory, algebraic systems, functions and applications, and probability. Additionally, all participants had successfully completed a three credit hour primary mathematics methods course prior to enrolling in this semester.

As a part of this second mathematics methods course, participants were engaged in a variety of experiences that were designed to help them think about the mathematical content and pedagogy of teaching of fractions. Fraction instruction started informally at the end of a class session with the question:

Consider the following three fractions: $\frac{99}{100}$ $\frac{6}{7}$ $\frac{15}{16}$

Which fraction is the largest? ___________

Explain the reasoning behind your choice.

The next class session started with a discussion of their responses and followed with activities and discussions involving comparing and ordering fractions.

Participants created the Marilyn Burns Fraction Kit and explored the cover-up and un-cover activities using the fraction kit (Burns, 2001) and additionally worked with a variety of tools (e.g. fraction bars and circles) used to aide students in fraction sense development. Students used these tools to demonstrate and solve a variety of fraction problems including writing and modeling (in at least three ways) fraction addition, subtraction, multiplication, division contextual problems.

One of the texts used for this course was *Developing Mathematical Fluency* (Wheatley & Abshire, 2002) which includes a variety of activities (e.g. fraction sequences, fraction two-ways, fraction balances) that aide in development of fraction sense and fluency with fraction operations. Each of these activities had a 1-2 page reading that supplied instructions and the pedagogical rationale for the activity. In addition, course readings included chapter sixteen from John A. Van de Walle‘s (2007) *Elementary and Middle School Mathematics: Teaching Developmentally* and a variety of articles from the NCTM journal *Mathematics Teaching in the Middle School* including Reys, Kim & Bay’s (1999) Establishing Fraction Benchmarks; Warrington’s (1998) Multiplication with Fractions: A Piagetian Constructivist Approach; and Nowlin’s (1996) Division with Fractions. As a part of the course, all of the prospective teachers were required to tutor an elementary student in grades 3 through 7 one hour per week for 10 weeks. During this experience, most prospective teachers worked with their tutee on fraction concepts.

A pre-test was administered during the class period prior to any instruction on fraction concepts and a post-test was administered at the end of the 15-week semester. The pre/post test contained 12 questions dealing with basic fraction concepts. Questions on the pre/post-test included

- 2 questions dealing with using benchmarks to determine size of fractions;
- 5 part-whole tasks (2 using an area model, 2 using a set model, and one contextual) (eg. If this rectangle is one whole, find one-fourth.);

$\frac{1}{5}$

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

PME-NA 2011 Proceedings

- 1 fraction sequence (Complete the sequence ___, ___, 4, ___, ___, 5 , ___);
- 1 pedagogy question that involved comparison of two fractions (each missing one piece); and
- 3 ordering fractions (1 set of unit fractions, 1 set with a common numerator, and 1 set with each fraction missing one piece).

Prior to data analysis the researchers determined how data would be coded (see Table 1). Then each question of the pre/post tests was analyzed independently by each researcher. Explanations were further analyzed for emergent themes using a constant-comparative method (Strauss & Corbin, 1998). The alpha level of significance of .05 was used for in inferential analyses.

Score	Scoring Explanation
0	Wrong Answer
1	Correct Answer, Incorrect Explanation
2	Correct Answer, Incomplete Explanation
3	Correct Answer, Complete Explanation

Table 1. Scoring rubric for questions with an explanation required

Results

The first two questions on the pre-post test involved students consideration of a pair of fractions (A. $\frac{1}{3}$ or $\frac{3}{4}$ and B. $\frac{5}{8}$ or $\frac{3}{4}$) and determining which of the two fractions were closer to ½ and to explain the reasoning for their choice. A paired t-test analysis revealed that students use of benchmark fractions to compare fractions revealed a significant increase in students understanding ($t(41)=-2.866$, $p=.006$) after fraction instruction. Further analysis (see Table 2) revealed that on their comparison of $\frac{5}{8}$ and $\frac{3}{4}$ an additional nine (21.4%) students scored had a correct answer with a complete explanation on the post-test while on their comparison of $\frac{1}{3}$ and $\frac{3}{4}$ an additional five (11.9%) students had a correct answer with a complete explanation on the post-test.

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

3	11(26.2)	16(38.1)	13(31.0)	22(52.4)

Table 2. Prospective teachers' scores on benchmark questions

Students' incorrect or incomplete explanations tended to focus the missing portion of the whole or how close they perceived the pieces were to ½ or 1 (See Figure 1).

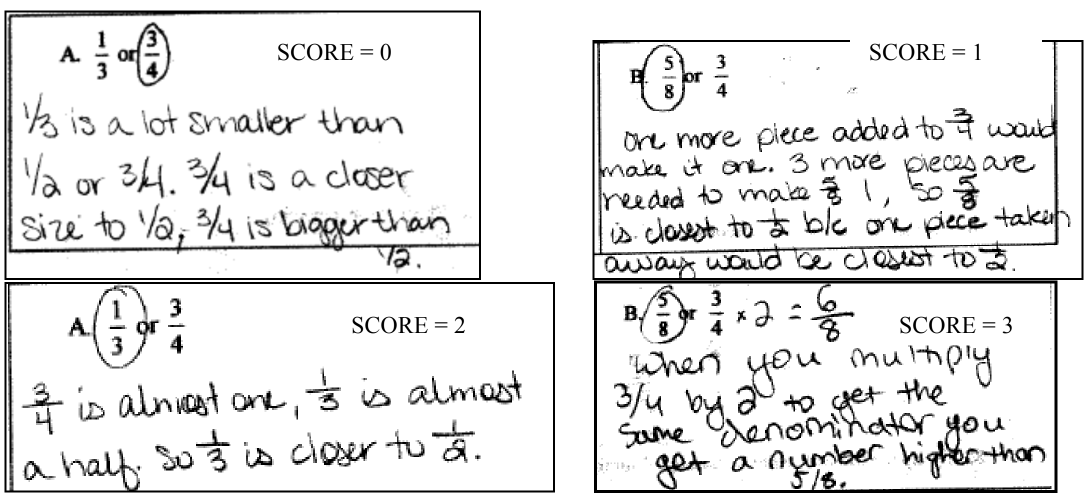

Figure 1. Sample scored benchmark responses

The next five questions on the pre-post test dealt with part-whole tasks – two area, two set, and one contextual. Participants were scored based on whether they had a correct answer or not. For the area and set tasks one dealt with fractional parts less than one and the other dealt with fractional parts greater than one. The contextual task required participants to draw a picture of a finished patio given a picture of ¾ of the patio. Examining student responses on the pre-test revealed that on both the area and set part-whole tasks students tended to be able to solve these when given the whole and asked to find an amount less than one; however when the amount given was greater than a one and asked to show one-whole, students struggled (see Table 3). Pre-post test paired t-tests revealed no significant difference for the area and set tasks when the given the whole and asked to find an amount less than one, but a significant difference ($t_{41} = -4.253$, $p = .000$) pre-test to post-test when the amount given was greater than a one and asked to

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

PME-NA 2011 Proceedings

show one-whole. Additionally, there was a significant difference (t_{41} = -2.672, p = .011) pre-post on the contextual task.

	Area <1		Area >1		Set<1		Set>1		Contextual	
	Pre	Post	Pre	Post	Pre	Post	Pre	Post	Pre	Post
M	1.00	1.00	0.43	0.83	0.98	0.98	0.43	0.79	0.50	0.71
SD	0.00	0.00	0.50	0.38	0.15	0.15	0.50	0.42	0.51	0.46

Table 3. Prospective teachers' scores on part-whole tasks

Approximately 12% (n=5) of the students could solve the fraction sequence ___, ___, 4, ___, ___, $5\frac{1}{5}$, ___ prior to the methods course but after exploring the teaching of fraction concepts nearly 60% (n=25) of the participants could solve the sequence. Statistical analysis showed this to be a significant increase ($t(41)$ = -.6.105, p < .001). It was disheartening to note that 40.5% (n=17) of the prospective teachers remained unsuccessful in solving the fraction sequence at the end of the course.

Participants were given the pedagogical scenario "A fourth grader said that 3/4 and 5/6 are the same size because they both have one piece missing. Do you agree? Explain." Students were scored on a scale of 0-3. Analysis of pre- and post-tests showed that about 24% (n=10) more of the participants had a correct answer and explanation. Further statistical analysis did not reveal a significant difference between participants the pre-test (M=190, SD=1.08) and their post-test (M=2.17, SD=1.21) scores.

Score	Pre-Test n(%)	Post-Test n(%)
0	5(11.9)	7(16.7)
1	11(26.2)	6(14.3)
2	9(21.4)	2(4.8)
3	17(40.5)	27(64.3)

Table 4. Prospective teachers' scores on pedagogical scenario

The final portion of the pre-post test required participants to order three sets of fractions (set of unit fractions, set with a common numerator, and a set with each fraction missing one piece). Table 5 shows the percent of participants that successfully ordered each of the sets of fractions. Paired t-tests revealed no significant difference when participants were asked to order a set of unit fractions. Significant differences were found when asked to order a set of fractions with a common denominator (t_{41} = -2.364, p = .023) and when the set involved fractions with one missing piece to make it a whole (t_{41} = -2.693, p = .010). A paired t-test involving the sum of participants scores on all three of the ordering fraction problems also revealed a significant increase (t_{41} = -3.650, p = .001) in students ability to order fractions from the pre-test to the post-test.

Discussion

This study revealed that this group of prospective elementary teachers brought with them a limited understanding of fractions to their mathematics methods courses and that despite a concentrated effort to improve those understandings, only minimal progress was accomplished. Although these prospective teachers had many years of school mathematics, including four college level mathematics courses and one primary level mathematics methods course, their reasoning about fraction concepts was often incorrect and largely based on limited understandings or misconceptions they had previously developed or, at best, understandings of fractions as part of a whole. If the strength of these pre-service teachers understandings lies only in a part-whole understanding of fractions then as mathematics educators we should be concerned. Lamon (2005) suggests that a part-whole understanding of fractions is not sufficient suggesting that when students' experiences have been limited to part-whole relationships they tend to have a limited understanding of fractions. Lamon recommends that students should be provided with a variety of experience to help them develop the multiple meanings of fraction.

Findings from this study demonstrated that many prospective elementary teachers are leaving their coursework with misconceptions such as seen in the ordering fraction problems and the pedagogical scenario a common misconceptions where students believe that when two fractions are missing one piece they are the same size fraction. As has been pointed out by NCTM (2000) "as students work with number, they gradually develop flexibility in thinking about numbers, which is a hallmark of number sense" (p. 80). Extending this to number sense about fractions, or fraction sense, students need to develop flexibility in their thinking about fractions (Reeder & Utley, 2007). The development of fraction sense is gradual and takes time to development, thus, it would too ambitious to imagine that the concentrated efforts during one semester to improve prospective elementary teachers fraction understand would result in significant progress. While prospective elementary teachers did make progress in developing their fraction sense they still need more opportunities to revisit fraction and other rational number concepts using pedagogical tools and teaching practices that help prospective teachers deepen and extend their fraction sense.

Ball (1990) points out that the types of experiences with learning and teaching mathematics that students have had when they reach their mathematics methods course(s) greatly impacts the influence that teacher educators can have in developing them into teachers of mathematics.

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

PME-NA 2011 Proceedings

Additionally, related to Ball's question suggesting that mathematics courses be examined, the results of this study further suggest that mathematics faculty responsible for the development and teaching of courses designed for prospective elementary teachers should be encouraged to collaborate with faculty teaching the mathematics methods courses to provide prospective teachers with more opportunities to develop their fraction sense. This study has important implications for mathematics teacher educators with regard to the kinds of challenges we face in improving not only our prospective teachers' content knowledge but their pedagogic knowledge as well.

CREATING ANALOGIES ABOUT EXPERIENCES IN ORDINARY LIFE WHEN DOING A PROOF BY CONTRADICTION

Gloriana González
University of Illinois at Urbana-Champaign
ggonzlz@illinois.edu

This paper investigates a geometry teacher's use of analogies about experiences in ordinary life when doing a proof by contradiction in an urban classroom. The analysis applies Systemic Functional Linguistics for examining how the teacher established connections between the source and the target of the analogies. The results show that the teacher created the analogies by using three different linguistic resources: lexical cohesion, conjunctions, and reported speech. The teacher's use of these linguistic resources intended to teach students how to formulate a mathematical argument by creating a parallelism in the grammatical structure of the analogies.

Introduction

The *Proof and Reasoning Standard* (NCTM, 2000) emphasizes the importance of increasing students' opportunities to engage in reasoning and proving. At the same time, the *Connection Standard* promotes the importance of establishing connections between students' experiences in mathematics classrooms and their experiences in ordinary life. One of the main goals of the high school geometry course has been to teach students to reason logically so that they can apply the same reasoning to situations in ordinary life (Fawcett, 1938). Current documents, such as the *Common Core Standards*, also stress the importance of teaching students to make mathematical arguments. In this paper, I show an example of a geometry teacher's use of analogies that drew upon experiences in ordinary life when doing a proof by contradiction in an urban classroom. The focus on proof by contradiction is relevant because research shows that students have difficulties with this type of proof (Lin, Lee & Wu Yu, 2003; Reid & Doubin, 1998). I apply analytical tools from Systemic Functional Linguistics (SFL) to examine the linguistic resources that the teacher used to create the analogies. An examination of teachers' practices that are intended to enable students to establish connections between arguments in ordinary life and mathematical arguments can lead to identify ways for helping students to develop their reasoning skills.

Theoretical Perspectives

Prior work in mathematics education has examined the use of analogies in mathematics teaching and learning (Bayazit & Ubuz, 2008; English, 1997; Greer & Harel, 1998; Reed, Ernst, & Banerji, 1974; Richland, Holyoak, & Stigler, 2004). Pimm (1981, p. 100) has offered a useful image of an analogy as a mathematical proportion (e.g., $A{:}B{::}C{:}D$) where one knows more information about one set of relationships (e.g., $A{:}B$) than about another one (e.g., $C{:}D$). The literature on cognition describes analogies as mappings from a base, B, to a target, T (Gentner, 1983). The base includes specific prior knowledge that constitutes the foundation of the analogy and the target includes the new knowledge that the analogy is supposed to make explicit.

In a study using data from 8th grade mathematics classrooms, Richland et al. (2004) showed that teachers, for the most part, assume the responsibility of selecting the analogies that they use in their explanations. This finding is important in light of research which suggests that two main components of an analogy affect children's ability to transfer what they know to the new concept that is the target of the analogy: *transparency* and *systematicity* (Gentner & Toupin, 1986). Transparency describes the degree of similarity between the objects that constitute the analogy, and systematicity involves the causal chains that connect the components of the analogy. For example, a teacher could say, "solving a linear equation is like taking off your shoes and your socks." This analogy has a low degree of transparency because a variable and a foot have little resemblance as physical objects. However, the analogy has a high degree of systematicity because the processes involved in the two cases are analogous: inverse operations are performed in the opposite order. The two aspects of the analogy that would need to be explicit for students are the mapping between the objects in the base and in the target and the causal links.

In order to examine how teachers achieve transparency and systematicity in their talk, I focus on the linguistic resources that teachers use to achieve cohesion (Halliday & Hasan, 1976). Cohesion includes the resources for making connections regarding the meanings in a text. I propose an operational definition of transparency and systematicity in relation to the linguistic resources used to achieve cohesion. I use lexical cohesion as a marker for transparency. Lexical cohesion involves making semantic connections in a text between chains of ideas that share similar meanings. A lexical cohesion chain can signal the transparency in an analogy because the types of word choices used when making an analogy can make explicit the relations that are established within the base and the target. In addition, I propose that speakers' use of resources from the system of conjunction is a marker of systematicity. In SFL, the system of conjunction includes words and terms that provide logical connections in a text such as "and" and "or," but also other conjunctions such as "however," "because," and "but" (Martin & Rose, 2003). I assume that the speakers' choices of conjunctions can signal the causal links between components of the analogy, thus showing whether the analogy has systematicity or not.

Research Questions

The research questions of this paper are the following:

1. How does a teacher use lexical cohesion to achieve *transparency* when using analogies?
2. How does a teacher use conjunctions to achieve *systematicity* when using analogies?
3. What other linguistic resources does a teacher use to map the source and the target of an analogy?

Mode of Inquiry

Data Sources

The main data sources for this paper are videos from a geometry lesson taught by Mr. Harrison in three different classes at Bondi High School, a large Midwestern urban school with an ethnically diverse population and with around 50% students from low SES background. For this paper, I selected videos where Mr. Harrison was proving the Angle-Side-Angle (ASA) triangle congruence theorem by doing a proof by contradiction in three regular geometry classes. I segmented the videos according to changes in the activity structure in each lesson, such as teacher exposition or triadic dialogue (Lemke, 1990). I selected the segments that included a discussion of a proof by contradiction to either motivate or *install* (Herbst, Nachlieli, & Chazan, 2011) the ASA theorem (e.g., the statement asserting that if two angles and the included side of one triangle are congruent to two angles and the included side of another triangle, then the triangles are congruent). These segments constituted the corpus of the paper.

Analysis

The selected segments were transcribed and parsed into clauses. I performed a lexical cohesion analysis with the purpose of identifying semantic chains in each segment. Then, I performed a conjunction analysis to identify the purpose of the conjunctions used in relation to the analogy. Finally, I analyzed the teacher's use of reported speech, as a result of my observations that this was another linguistic resource that the teacher deployed. Reported speech has the purpose of attributing to a source what someone would think or say, and it is a resource from the system of engagement in SFL (Martin & White, 2005).

Description of the Class Discussion and the Analogies Used

In the three lessons, Mr. Harrison's discussion followed a similar structure. First, he requested students to provide an example of a situation where they had been falsely accused of doing something, and he elaborated what would be a proof by contradiction of that false accusation. Then, he provided the proof by contradiction to prove the ASA theorem. Finally, he made the analogy explicit by stating how the proof for the ASA theorem was similar to the argument against the false accusation. The following transcript from the 1st period class shows an example of how Mr. Harrison elicited students' experiences:

> *Mr. Harrison*: So, have you guys ever made an argument where somebody says something and you're like [pause 3 seconds] how do I say this? You say, well, if that was true, then, this, this, and this happens. Like, somebody claims, I don't know. Can somebody give an example of that? Like a real life example? Maybe somebody accuses you of, I don't know, cheating on somebody. Or, somebody accuses you of doing something you didn't do. And your argument against that is like, "Well, if that were true, then…". You guys?

In this excerpt, Mr. Harrison provided the case of "cheating on somebody" to model the type of accusations that students could have been subject to. Mr. Harrison also started phrasing what an argument against that accusation would look like by saying, "Well, if that was true, then…". This phrasing provided the basis for the argument in the proof by contradiction.

Table 1 shows a list of the base knowledge in the analogies that the students shared. In some classes, the students hesitated to provide an example from their own lived experiences and the teacher asked students to make up a story (1st and 4th period classes).

Class period	**What is the base knowledge?**	**Evidence for the contradiction**
1	Being accused of fighting someone.	The accused person does not have a black eye.
4	Being accused of initiating communications with a friend's ex-boyfriend.	The date of the text messages shows that the ex-boyfriend initiated the communication and not the accused person.
6	Being accused of shoplifting.	The accused person's bag is empty.

Table 1. Examples provided for the analogies

In the three classes, the teacher provided the same proof by contradiction of the ASA theorem. The proof started by assuming that a pair of triangles (ΔABC and ΔDEF in Figure 1) is not congruent, even though two pairs of angles and the pair of segments included between those angles are congruent. Without loss of generality, $\overline{AB}$ must be longer than $\overline{DE}$. Then, one can assume that there is a point M on $\overline{AB}$ where $\overline{AM} \cong \overline{DE}$. Consequently, the triangles would be congruent by the Side-Angle-Side theorem, since $\overline{AM} \cong \overline{DE}, \angle MAC \cong \angle EDF, \overline{AC} \cong \overline{DF}$. However, there is a problem with this conclusion, because the angles BCA and EFD were supposed to be congruent, and, as a result of the triangle congruency, the angles *MCA* and *EFD* would also be congruent. This would mean that the angles *BCA* and *MCA* are congruent, but one angle is obviously bigger than the other one. Therefore, the original assumption is false and the triangles are indeed congruent.

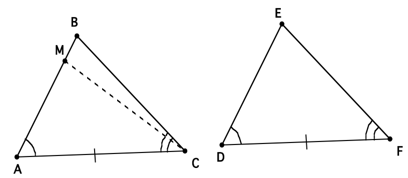

Figure 1. Diagram for the proof of the ASA theorem

Results

Using Lexical Cohesion to Achieve Transparency

The analysis of lexical cohesion intended to look for chains of semantic terms that were used to create the analogy. According to Halliday and Hasan (1976), there are two main types of lexical cohesion: reiteration and collocation. Reiteration involves the repetition of a term, the use of synonyms, the use of a general word (e.g., "Angle-Side-Angle" and "rule") or the use of a superordinate term to denote a broader category of another term (e.g., "proof" and "proof by contradiction"). Collocation involves a relation that is not equivalence, but another type such as complementarity or hyponymy (e.g., class and part). Table 2 shows the results for the analysis of lexical cohesion chains for repetition and synonymy. The coding for general word and superordinate did not yield any cohesion across the two contexts and is not included here.

Class period	Type of reiteration cohesion	Terms used		Frequency in the mathematical argument	Frequency in the non-mathematical argument
1	repetition[1]	argument		1	7
		problem		5	0
		rule		6	0
		true		1	5
1	synonym	argue and prove	argue	0	1
			prove	1	0
		claim and accuse	claim	1	1
			accuse	0	1
4	repetition	accuse		5	7
		show		6	4
4	synonym	argue and show	argue	2	2
			show	6	4

[1] For sake of brevity, I only show terms that were repeated more than 5 times.

Class period	**Type of reiteration cohesion**	**Terms used**		**Frequency in the mathematical argument**	**Frequency in the non-mathematical argument**
		contradiction and wrong	contradiction	3	0
			wrong	3	1
		proof, argument, and strategy	proof	2	0
			argument	2	1
			strategy	2	0
6	reiteration, repetition	accuse		1	5
		assumption		3	3
		show		4	1
		true		0	7
6	reiteration, synonym	argue and show	argue	0	2
			show	4	1
		assume and pretend	assume	0	1
			pretend	1	1

Table 2. Analysis of reiteration cohesion

The lexical cohesion analysis demonstrates that some terms throughout each lesson provided a common reference to talk about the examples that the students provided and also about the mathematical proof. The use of the same terms for non-mathematical and mathematical arguments provided a cohesive effect. For example, in the 4th period class, the teacher used the word "show" a total of 10 times with three main purposes: (1) to announce the proof of the ASA theorem (e.g., "During this proof that I'm about to **show** you I don't want you to write anything down), (2) to model how to provide the evidence of the contradiction (e.g., "And you **show** her your phone"), and (3) to state the contradiction in the proof (e.g., "That's kind of like me **showing**, or you **showing** the text messages…"). By using repetition Mr. Harrison provided a link between the mathematical and the non-mathematical argument when creating the analogy, thus achieving transparency.

Collocational cohesion was useful for naming the different components of a proof by contradiction when talking about the non-mathematical context and, also, when talking about the theorem (see Table 3). For example, in response to the student's example about being accused of initiating a conversation with the ex-boyfriend of a friend, Mr. Harrison said, "So, how do you **argue** that you've been **accused wrong**?" Here, Mr. Harrison framed the formulation of an argument as a strategy for refuting a false accusation. Mr. Harrison used a similar collocation of terms when introducing the proof for the ASA theorem. He said, "You guys wanna know why Angle-Side-Angle works? I can **show** you and you're gonna **show** the same kinda **argument strategy**." Then, later he said, "So, here's the **strategy**… Okay, somebody **accuses** me and says, 'Hey, these triangles aren't congruent." Collocational cohesion enabled the teacher to achieve transparency by labeling different components of the proof by contradiction such as the claim that would be contradicted (e.g., the accusation), the assumption, the contradiction (e.g., the problem), and the proof by contradiction (e.g., the argument strategy). The transparency in the text involved the mapping between the use of one term in the context of the example provided by the student and the use of the same term used in the context of the proof of the ASA theorem. Therefore, Mr. Harrison's explanation of the proof made the strategy explicit by using the same language of an accusation to bridge the two contexts.

Class period	**Terms used**
1	accuse, argue, argument, claim, convince, logic, problem, prove, true, wrong
4	accuse, argue, assume, proof by contradiction, show, strategy, true, wrong
6	accuse, argue, assume, assumption, logic, pretend, problem, proof, show, train, true, wrong

Table 3. Analysis of collocational cohesion

Using Conjunctions to Achieve Systematicity

According to SFL theory, conjunctions can help establish four main types of logical relations: addition, comparison, time, and consequence (Martin & Rose, 2003, p. 127). There are two main types of conjunctions according to their purpose. External conjunctions help to establish logical relationships in terms of the meanings conveyed in a text. Internal conjunctions have the function of organizing a text. Table 4 shows the results of the coding according to the logical relations that the conjunctions established. The teacher used more external conjunctions than internal conjunctions. Therefore, the analysis focuses on the external conjunctions that the teacher used, because these were the ones mostly used to create the arguments in the analogies.

Class period	**Addition**		**Comparison**		**Time**		**Consequence**	
	External	Internal	External	Internal	External	Internal	External	Internal
1	30	13	6	0	0	0	62	0
4	19	13	8	0	0	0	33	0
6	26	12	4	0	0	0	38	0

Table 4. Conjunction analysis

Most of the external conjunctions that the teacher used showed a logical relation of consequence. The conjunctions for consequence (i.e., *because*, *so*, *therefore*, *if*, and *then*) were useful to connect the logical chain of steps in the proof by contradiction. There are four types of conjunctions to denote consequence according to their purpose: cause, means, condition, and purpose. Most of the conjunctions to denote consequence that Mr. Harrison used had the function of showing cause (23 in the 1st period, 16 in the 4th period, and 25 in the 6th period). For example, when Mr. Harrison identified the contradiction in the proof of the ASA theorem in the 1st period class, he said, "**So**, there's a problem with that. There's a problem with the idea that the triangles are not equal. **So**, when this is happening, you say, 'Well, guess what, you were wrong when you said that the triangles are not equal.'" Mr. Harrison used "so" to denote the causal links between the problem (e.g., the contradiction) and the consequences of the problem, and, also, between the consequences of the problem and the conclusion of the proof (e.g., the assertion that the triangles are not equal is false). The use of conjunctions to denote cause strengthened the causal links, thus enabling the teacher to achieve systematicity.

The second most frequent type of conjunction used were conjunctions to denote addition. The predominance of conjunctions with a logical relation of addition is not surprising, since "and" is included within this type of conjunction, which is one of the most common conjunctions in the English language (Martin & Rose, 2003, p. 113). In the segments under investigation, "and" was the conjunction most used with the purpose of adding clauses (23 times in the 1st period, 17 times in the 4th period, and 24 times in the 6th period).

The conjunctions to denote comparison were the third most frequent conjunctions. These conjunctions had the function of establishing the analogy between the examples from experiences in ordinary life and the proof of the ASA theorem. The only conjunction used for comparison was "like." For example, the teacher said, "Okay, so somebody accuses me and says, 'Hey, these triangles aren't congruent.' It's kinda **like** somebody accusing, you know, Lena, talking to this guy first or whatever." The use of "like" here, intended to establish the link between the two examples, thus making the analogy explicit. The use of the conjunction "like" to connect the two proofs is an example of how the teacher used conjunctions to map the causal chains in the base and in the target of the analogy.

Using Reported Speech

Another linguistic resource that enabled the teacher to create the analogy was the use of reported speech. The teacher assumed the voice of an accused person when discussing the example, and, also, when proving the theorem. The transcript below shows how the teacher used reported speech in the 6th period class.

> *Mr. Harrison*: Let's take your example, somebody accuses you of shoplifting. One option could have been to say, "Hey, let's go ahead and pretend that I did shoplift for just a second. If I shoplifted, then you would expect to see something in my bag, or somewhere on me. Well look in my bag; it's empty. So, guess what, I didn't shoplift."

Mr. Harrison also enacted how to argue against the accusation that the triangles are not congruent by ASA theorem, as shown in the transcript below.

> *Mr. Harrison:* So, I'm like, "Alright, let's pretend that they're not equal, for just a second. If they're not equal, then maybe these two pieces would not be equal. So maybe *DE* is shorter."

Table 5 shows the number of clauses stated by the teacher that include reported speech to make the arguments in each class. The use of reported speech helped the teacher to engage students in a hypothetical dialogue that provided evidence against a false accusation using a proof by contradiction. The teacher applied the same structure of a dialogue about an event in ordinary life to a hypothetical dialogue with mathematical content, thus making the analogy explicit.

Class period	Clauses that use reported speech in the mathematical argument	Clauses that use reported speech in the non-mathematical argument
1	12	7
4	21	12
6	8	17

Table 5. Clauses with reported speech

Discussion

The interplay of three linguistic resources, specifically, lexical cohesion, conjunctions, and reported speech, provided the structure to model a proof by contradiction. These three resources allowed the teacher to create a sort of template that he could apply to build a proof by contradiction regardless of the content (e.g., mathematical or non-mathematical). Figure 2 shows a model for the structure of the argument. This model takes into account the different linguistic resources that helped him to establish the analogy by establishing a *parallelism* in the grammatical structure (Martin & Rose, 2003, p. 237). The parallelism was achieved by using repetitions and synonyms, by voicing the "accusations" in a similar way through reported speech, and by using conjunctions to connect causal links within each analogy.

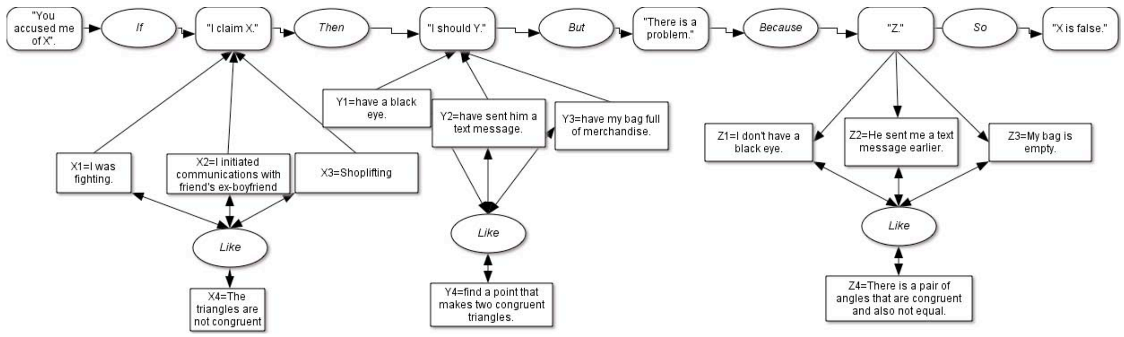

Figure 2. Model for the structure of the analogies

The goal of teaching geometry as a vehicle to teach students how to apply logical reasoning in situations of ordinary life continues to be a goal today. By allowing students to draw upon their prior knowledge of ordinary situations through the use of analogies, teachers can broaden students' opportunities to learn and instill in students an appreciation for mathematical thinking.

THE EFFECTS OF AN ADVANCED HIGH SCHOOL COURSE IN NUMBER THEORY AND ALGEBRA ON STUDENTS' MATHEMATICAL SELF-EFFICACY

Cher C. Hendricks
Georgia Institute of Technology
cher.hendricks@ceismc.gatech.edu

Richard S. Millman
Georgia Institute of Technology
richard.millman@ceismc.gatech.edu

The purpose of this study was to determine ways high school students' mathematical self-efficacy was affected by participation in an advanced course in proofs and problems in number theory and algebra. In the course, emphasis was placed on students engaging in higher order mathematical thinking and developing mathematical habits of mind. Because self-efficacy affects goal setting and perseverance in the face of challenging tasks, which ultimately affects achievement, we were interested in determining students' course goal self-efficacy at the beginning of the course and whether self-efficacy changed as a result of course participation.

Introduction

In this research report, we describe ways high school students' mathematical self-efficacy was affected through participation in an advanced course titled *Proofs and Problems in Number Theory and Algebra* (PPNTA). In the larger study that supports this brief report, we will examine students' understanding of and skill in constructing valid proofs within the backdrop of number theory and algebra. We are further interested in the ways PPNTA course participation increases students' mathematical habits of mind. The study will ultimately result in three years of data, enabling the authors to track longitudinal trends and a number of different foci, both in pedagogy and content.

In this advanced course, students were expected to engage in higher order mathematical thinking and develop proof construction and problem solving ability, as well as an understanding of the notion of a mathematical habit of mind. Thus, the goals of the course were not content-specific but instead focused on ideas such as elegance in proofs and solutions and metamathematics. In addition, students were expected to increase their skill in engaging in intellectual argument with others about mathematics and to work individually and in teams to solve complex problems in algebra or number theory.

Students in this course are academically gifted and have demonstrated high achievement and high mathematical self-efficacy in courses with content-specific objectives. However, it is unclear whether these efficacy beliefs would be similar in a course such as PPNTA where goals are focused on engaging in mathematical habits of mind (MHM) and the construction of proofs. While there is not an agreement on what the MHM phrase means, it would certainly include 1) to explore mathematical ideas, 2) to formulate questions, 3) to construct examples, 4) to identify problem solving approaches that are useful for large classes of problems, 5) to ask whether there is "something more" (a generalization) in the mathematics on which students are working, and 6) to reflect on answers to see whether an error has been made (Millman & Jacobbe, 2008, 2009). These six traits help define a term that is featured prominently in an important report on the mathematical education of future teachers (CBMS, 2001). In addition, MHM is closely linked to the Polya Principles of Problem Solving.

For all students of mathematics, there is a real difference between studying a topic (such as calculus), which includes both manipulation and conceptual understanding, and the ability to engage in the kind of abstract thinking that is required in writing proofs. Because self-efficacy plays a critical role in the ways individuals approach difficult tasks, set goals for themselves, and persevere when faced with a challenging problem (Bandura, 1994), we were interested in determining students' course goal self-efficacy at the beginning of the course and whether self-efficacy changed as a result of participating in the course.

Theoretical Framework

Self-efficacy refers to the beliefs individuals hold about their capability to achieve a certain level of performance on a given task or goal (Bandura, 1994). These self-referent beliefs influence actions, and, as Pajares and Schunk (2001) explain, self-efficacy is a better predictor of what individuals accomplish than are their actual capabilities. Self-efficacy determines what people choose to do, how much effort they put into a task, and whether they persist when challenged (Pajares & Schunk).

A number of studies have shown a positive relationship between self-efficacy and academic achievement. Multon, Brown, and Lent's (1991) meta-analysis of 68 self-efficacy studies conducted between 1977 and 1989 indicated a positive correlation between self-efficacy and academic achievement. Further, according to Zimmerman (1995), other research reveals a causal link between self-efficacy and academic achievement (see, for example, Barry, 1997 and Schunk, 1981, 1989).

The causal link between self-efficacy and achievement is seen as a reciprocal relationship. As Pajares and Schunk (2001) explain, "According to Bandura's social cognitive theory, behavioral and environmental information create the self-beliefs that, in turn, inform and alter subsequent behavior and environments" (p. 251). Thus, self-efficacy can be positively influenced by engaging in classroom activities that increase students' competence (including modeling, providing feedback, and strategy training), and as self-efficacy is built through these types of activities, academic achievement can also increase. As described in Pajares and Schunk's overview of self-beliefs and school success and Zimmerman's (1995) review of self-efficacy and educational development, this reciprocal relationship has been demonstrated in numerous studies.

Methods

PPNTA Course

The course was developed as a collaborative effort between the Georgia Institute of Technology and a local charter high school for mathematics, science, and technology. The course instructor was a Georgia Tech graduate student in mathematics and computer science who earned a bachelor's degree in mathematics with highest honors. His previous teaching experience consisted of two years as a teaching assistant for undergraduate calculus courses.

Georgia Tech's Center for Education Integrating Science, Math, and Computing (CEISMC) financially supported the teaching of the course through a research assistantship funded through Georgia's Race to the Top award, which was funded by the U.S. Department of Education. The director of CEISMC, who is co-author of this paper, had a major role in planning the PPNTA course. In addition to co-authoring the course textbook, he also made classroom observations over the course of the semester and delivered lectures in the areas of introduction to proofs, the use of groups in geometry, and the notion and use of equivalence classes.

The PPNTA course was conceived as an introduction to mathematical proofs using the subjects of number theory and algebra as context. In the course, students were introduced to mathematics as a living research discipline that can be used to discover new ideas about numbers, space, functions, and other objects as well as their inter-relationships. It was designed as an “explore, generalize, prove, think” environment in which students approached mathematics much differently than in a traditional math classroom. In some ways, this type of environment is similar to the culture of doing mathematical research. The purpose was to help students understand that mathematics is not fundamentally about calculation nor is it based on rote memorization. The philosophy of the course is aligned to the National Council of Teachers of Mathematics (NCTM) Principles and Standards.

Students attended class Monday through Friday for 18 weeks. Class periods were 48 minutes. Class activities included instructor lecture, reviewing problem sets, students working problems independently or in groups, and students making presentations to the class as a whole.

Goals for students were to: (1) identify what makes a mathematical proof correct, (2) identify flaws in fallacious proofs, (3) learn some commonly applied proof techniques, (4) become proficient at reading and writing mathematics in general and proofs in particular, and (5) practice applying problem solving methods to find solutions and demonstrate clearly their correctness. Topics covered during the course were:

- Basic properties of the integers
- Divisibility and prime numbers
- The Fundamental Theorem of Arithmetic
- Diophantine equations
- The idea of equivalence relations and its applications
- Basic properties of polynomials
- Divisibility of polynomials, divisibility methods, and the roots of polynomials
- Applications to combinatorics

One example of how students were to explore mathematics and its ideas was a section (covered in the third week) in which the instructor first worked with students to show that the $\sqrt{2}$ is irrational using the usual proof by contradiction. The students were then asked to fashion a proof of the fact that $\sqrt{3}$ is irrational using the logic of the $\sqrt{2}$ example. From this approach, they were asked to generalize the procedure so that it was valid for the square root of any prime number. In order to understand what is really going on in this proof structure, we asked the students to prove that the $\sqrt{4}$ was irrational. Of course, they all knew it was false, but having the students figure out why the “proof” of $\sqrt{4}$ is irrational must be incorrect was important for truly understanding what a proof is and what it isn’t.

Participants

Participants were 15 students (14 seniors and 1 junior) enrolled in the PPNTA course at a local charter high school with a focused curriculum in math, science, and technology (18 total students were enrolled; 15 agreed to be in the study). Eleven students were male and four were female. Ten students were Asian and five were Caucasian. Students had completed every high school math course available to them except for AP statistics, and all but one had taken two semesters of calculus (Calculus II and III at Georgia Tech) beyond AP Calculus and differential equations prior to enrolling in this course. All students were planning on majoring in a STEM or premedical field once enrolled full time in college. All participating students in this study earned an A as a final course grade in the PPNTA class.

Setting

The school where the study took place is a public, charter high school for mathematics, science, and technology whose first courses were given in 2007. The new campus, opened in 2010, includes high-tech classrooms and project-based work areas for student, university, and business collaboration. All eighth grade students in the county may apply for admission to the school, but due to a high number of applicants, a lottery is used to determine which students will be admitted. Enrolled students choose one of three areas in which to focus their studies: engineering, bioscience, or emerging technologies. Advanced Placement (AP) courses are offered in calculus (AB and BC), statistics, physics (mechanics and E&M), biology, chemistry, and computer science, as well as in the humanities. Math courses are offered in accelerated integrated geometry and accelerated integrated pre-calculus (courses that are aligned to the state mathematics curriculum), in Calculus 2 (which includes linear algebra), and in Calculus 3 (both taught via video conferencing with Georgia Tech). Courses in differential equations and PPNTA are also offered. In 2009, the school's total enrollment was 327 students; 16% were economically disadvantaged and 2% had identified disabilities. Standardized test data indicate high percentages (> 90%) of students meet or exceed standards.

Data Collection

To answer the research question *In what ways does participation in the Proofs and Problems in Number Theory and Algebra course affect students' mathematical self-efficacy?* we measured mathematical self-efficacy using a pre and post self-efficacy instrument. In designing the instrument, we relied on Bandura's *Guide for Constructing Self-Efficacy Scales* and tied items to specific course goals. As Bandura suggested, we phrased items on the pre- and posttest in terms of what students *can* do in order to measure perceived capability. We extended this by asking students on the pretest to provide an additional measure of how capable they were to achieve each goal. Though Bandura cautions against asking individuals to judge potential capabilities, we chose to include the extended items on the pretest because students had not yet had opportunities to develop ability in most of the course goals, which was likely to result in low self-efficacy measures. Measuring both current and potential capability on the pretest allowed us to make additional comparisons that enhanced the meaningfulness of results.

On the pretest, students ranked their self-confidence on a scale of 0 to 100 (with 100 being most confident) on how confident they were that they could already complete the task (e.g., *understand the importance of proofs in mathematics*) and how confident they were that they could learn to do the task. For the posttest, students responded to the same prompts to rate how confident they were in their ability to complete each task. We chose the 0 to 100 scale based on Bandura's suggestion to use a broad scale to increase measurement sensitivity and reliability. The pretest instrument is provided in Appendix 1.

Students also completed a post-course survey about their experiences in the PPNTA course. The survey included self-efficacy items that provided students with the opportunity to describe the ways in which their confidence had changed, if at all, due to completing the course and the aspects of the course that affected their confidence. All students provided open-ended responses to the self-efficacy items.

Results and Discussion

Overall means for (1) the pretest in which students rated confidence in their ability to already complete each course goal (prior to the class beginning), (2) the pretest on students' confidence they could achieve the course goals, and (3) the posttest on students' confidence in their ability to accomplish each course goal (at the end of the course) are provided in Table 1. The difference between the pre measures was statistically significant ($t_{14} = -9.26$, $p < .000$) and indicated that although students began the course with low self-efficacy, their efficacy regarding their ability to learn content and accomplish the course goals was significantly higher. The standardized effect size for the difference was 1.37, indicating a large effect. There was no significant difference between students' confidence they could accomplish the course goals and their confidence at the end of the course. The 29.16-point difference between the pre- and posttest measures of self-efficacy was significant ($t_{14} = 5.59$, $p < .000$), and the effect size (1.70) was large.

Table 1. Student Self-Efficacy Beliefs on Course Goals Pretest

Item	N	Confident in ability to x	SD	Confident can learn to x	SD	Diff	Sig
understand importance of proofs in mathematics	18	63.8	25.6	91.2	9.0	27.3	.000
know how to work in teams to solve problems from number theory and algebra	18	63.4	27.7	92.7	10.1	29.3	.000
know how to use concepts learned about algebra in other courses in this course	18	49.9	29.9	81.8	20.2	31.8	.000
understand the concept of "elegance" in proofs	18	47.7	29.9	78.2	21.6	30.1	.000

Appendix 1. Mathematics Self-Efficacy Pretest

The table below lists goals for the course in the MIDDLE COLUMN. Read the goal and then, in the LEFT COLUMN, mark how confident you are that you can already do this or have already reached that goal. In the RIGHT COLUMN, mark how confident you are that you can reach the goal. In each column, rate your degree of confidence by recording number from 0 to 100 using the scale given below:

0	10	20	30	40	50	60	70	80	90	100
Cannot do at all					**Moderately can do**					**Highly certain can do**

Here's an example:

How confident are you that you can already do this?	Goal	How confident are you that you can learn to do this?
write in a number between 0 and 100		write in a number between 0 and 100
35	**Arrange a place to study without distractions.**	**80**

This means less than moderately confident one can already arrange a place to study without distractions.

This means between moderately and highly confident one can learn to arrange a place to study without distractions.

How confident are you that you can already do this?	Goal	How confident are you that you can learn to do this?
write in a number between 0 and 100		write in a number between 0 and 100
	Understand the importance of proofs in mathematics.	
	Learn different methods to construct proofs.	
	Understand the concept of "elegance" in proofs.	
	Create examples that provide insight into designing proofs.	
	Construct valid proofs.	
	Identify the fallacious reasoning in incorrect proofs.	
	Engage in intellectual arguments with others about mathematics.	
	Explain ideas that motivate your proofs.	
	Use concepts learned about elementary number theory and algebra in other courses to solve problems in this course.	
	Work individually to solve mathematical problems from number theory and algebra.	
	Work in teams to solve mathematical problems from number theory and algebra.	
	Define what "mathematical habit of mind" means to you.	
	Develop a mathematical habit of mind.	

TRACING THE DEVELOPMENT, DURABILITY AND DISSEMINATION OF MILIN'S INDUCTIVE ARGUMENT

Manjit K. Sran
Rutgers University
Manjit.Sran@monroe.k12.nj.us

Carolyn A. Maher
Rutgers University
Carolyn.Maher@gse.rutgers.edu

This case study documents the development, durability and dissemination of an inductive argument built by a nine-year-old student, Milin, over a 13 month period spanning his fourth and fifth grade years. He investigated counting problems whose solutions were represented with a variety of representations that he successfully linked together and used to convince his classmates and researchers of the validity of his arguments. This study provides a detailed analysis of Milin's problem solving. It shows the durability of his understanding over time and the impact his reasoning had on his classmates as his ideas traveled within the class.

Introduction

There has been considerable work done over the last decade that has established the power of children's reasoning (Maher, Powell, Uptegrove, 2010). Given certain conditions and tasks, children naturally engage in thoughtful problem solving and demonstrate their mathematical understandings using a variety of representations. By making use of their representations, learners are empowered to make convincing arguments for their solutions (Sran, 2010). This study adds to the literature by tracing, in detail, the building of an inductive argument by Milin, a nine-year old student. He worked in a variety of settings, first with a partner, then a small group. He shared his solutions with his classmates and during task-based interviews. We present eight episodes to trace how Milin developed, sustained and shared his justification for the solution of a counting problem using an inductive argument and how his ideas spread within the classroom. The research questions that guided this study are:

1. How did Milin build his inductive argument?
2. How did his argument travel to other students?

Theoretical Framework

In the last two decades, increasing attention has been given to how mathematical understanding is acquired (Davis, 1984; Davis, 1992; Maher & Davis, 1995). This has resulted in a shift of attention from rule-based learning to meaningful learning. Davis (1984) indicates that "understanding" involves building schemes and fitting new ideas into existing ones. Learning can take place while working on new problems and making use of personal representational systems such as spoken and written language, physical models, drawings and diagrams, and mathematical notations. According to Davis and Maher (1990), new ideas can emerge from previous knowledge already acquired. Hence, understanding can be achieved when a learner fits the new ideas into already existing schema. Davis (1984) uses a metaphor of a jigsaw puzzle to illustrate how this learning might occur. For problems requiring solutions for which the learner lacks fully developed schema, new experiences are needed. According to Maher (1998), the *building blocks* for new schema come from an individual's experiences, and so when students work with new problems, they have the opportunity to use more elaborate and sophisticated representations to build and expand their knowledge (Maher, Martino & Alston, 1993).

Yackel and Hanna (2003) have emphasized the social aspects of reasoning, pointing to the importance of communal activity where learners have the opportunity to interact with others. In the process of sharing and justifying solutions to problems during small group work, individual interviews, group interviews, or classroom discussions, the students' ideas are made public. Maher and Martino (2000) identified several conditions that promote a culture of *sense-making*.

Methods

Data were collected from three main sources. The video recordings serve as the primary source of data for this study. Cameras were used to capture the conversations and written work of the students. The second data source is students' written work. A third source consists of individual and small group interviews and observer field notes. Multiple data sources allow for triangulation and help ensure the validity of data analysis.

Milin and his classmates engaged in variations of the Tower Problems that (1) asked them find all possible towers of a given height when selecting from cubes of two colors and (2) come up with a convincing argument for the solution.

Analysis for the present study uses components of a model described by Powell, Francisco, and Maher (2003). All video sessions were transcribed, coded and verified by an independent researcher. The video clips that accompany these episodes can be accessed at http://www.video-mosaic.org/.

Results

In the course of Milin's earlier explorations with towers, several strategies were identified. These included guess and check, opposite by color, opposite by inverting, staircases, elevators, and organizations by groups with similar attributes (Sran, 2010). For this report, we describe Milin's problem solving in which he generated taller towers using smaller ones, and building a *family tree.* Using the strategies that took on a variety of representations including physical models, verbal explanations and diagrams, Milin formulated and applied an effective inductive argument to justify an earlier conjecture of a *doubling* rule.

Episode 1: February 6, 1992

Milin and his classmates completed their building of five-tall towers as a classroom activity. The researcher (R1) asked students to think about an assertion made by some children that there were exactly ten towers with two red cubes, displaying the student models in front of the class (see Figure 1). She asked whether two red cubes could be separated by three yellow cubes another way. Milin immediately responded: "On ones there is only three. On two's there is only two. And on threes there is only one." He then commented that no others could be built.

Figure 2. Collection of all five-tall towers with exactly two red cubes

Episode 2: March 6, 1992

A month later, after Milin had worked on five-tall towers, he shared with R2 his continued work on the problem. He shared his record of the number of towers of varying heights (see

Figure 2) and explained to R2 that there were two one-tall towers, four two-tall towers, eight three-tall towers, and so forth.

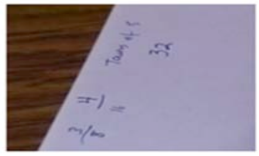

Figure 3. Milin's written record of his towers of various heights

When R2 asked about what the towers of one and two-tall would look like, Milin built all one and two-tall towers. R2 asked Milin to elaborate further, and Milin showed how taller towers could be generated from smaller ones. He placed his one-tall black tower in front of the two-tall towers with black bottoms (see Figure 4). R2 asked about three-tall towers and in response, Milin generated these towers by first placing a cube of one color on top of each one of the four two-tall towers and then made the remaining four three-tall towers by placing the cube of the second color to each two-tall tower. As he placed these new towers next to the matching two-tall tower he responded: "See … That would go into this family." Milin continued to use the term *family* throughout this interview as he arranged taller towers next to the corresponding shorter towers (see Figure 4). He remarked that the same strategy would work for four-tall towers.

MILIN: Yeah. Two for this, two for this, two for this, two for this , two for this, two for this, two for this. *(Milin points to each of the towers of three)*

R2: Yeah

MILIN: And once you get to 16 *(Milin points to the column with 5 and 32 on his paper)* you get all of them and you get 32.

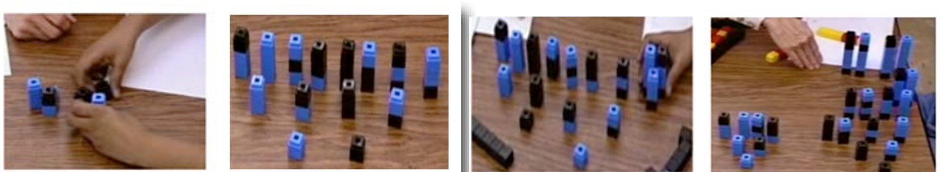

Figure 4. Milin explains and builds his "family" strategy

Episode 3: March 6, 1992

At this point, Milin reported finding 50 six-tall towers using organizations by categories. More convinced of the doubling pattern, he reflects on his earlier work, suggests that he did something wrong, and conjectured that there should be 64 six-tall towers.

MILIN: But, I think I did something wrong on umm from 32 to go to 6[*six-tall towers*]. I think I did something wrong.

R2: Why?

MILIN: Mmm, I don't think that pattern would break down like.

R2: You really don't? You...

R1: *(off-camera)* Ah-ha

R2: If it didn't break how many should there be?

MILIN: Uh, 64

Episode 4: March 10, 1992

Four days later, Milin introduced his doubling argument to justify his solution for towers of varying height to three of his classmates (Maher & Martino, 1996a). In response to the researcher's question about the number of six-tall towers Milin said:

MILIN: Probably 64.
R1: Why do you think 64?
MILIN: Well, because there was a pattern.
R1: What's that?
MILIN: You just times them by two

When the researcher asked why the towers were doubling in each successive height, Milin offered the following explanation: "For each one of them you could add one no two more for on because there is a black I mean a blue and a red." R1 then asked the group to justify the eight three-tall towers, when selecting from two colors. Milin again explained that each two-tall tower could be turned into two three-tall towers as shown in Figure 4.

MILIN: Yeah. You have to keep on putting two for this two for this two for this and two for this and it will work out.
R2: Do you agree with that Jeff?
JEFF: Yes.
R2: Okay. So-
MILIN: Because you can't. There is only two colors you can't put any more on them.
R2: Now imagine we have our eight. Where do we go from eight? Because I heard Michelle say twelve.
MILIN: Sixteen.

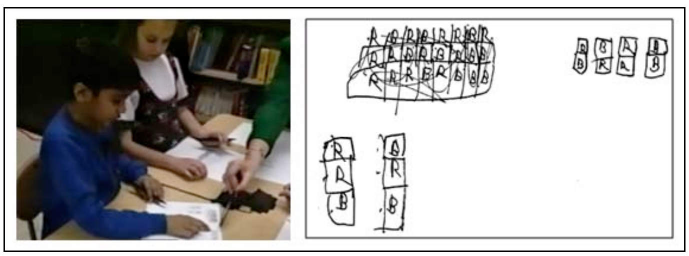

Figure 5. Milin shows how there are only two possible three-tall towers from each two-tall tower

Milin now expressed certainty that this "doubling" pattern would continue, in contrast to his doubt expressed in the earlier session. He continued:

MILIN: And for each one you keep on doing that. And for six you get sixty four.
R1: Does that make any sense?
JEFF: Yeah
MILIN: It follows the pattern to five why can't it follow the pattern to six?

Episode 5: October 25, 1992

Eight months later, Milin's response to the written assessment bears a remarkable resemblance to his *family* strategy (see Figure 6).

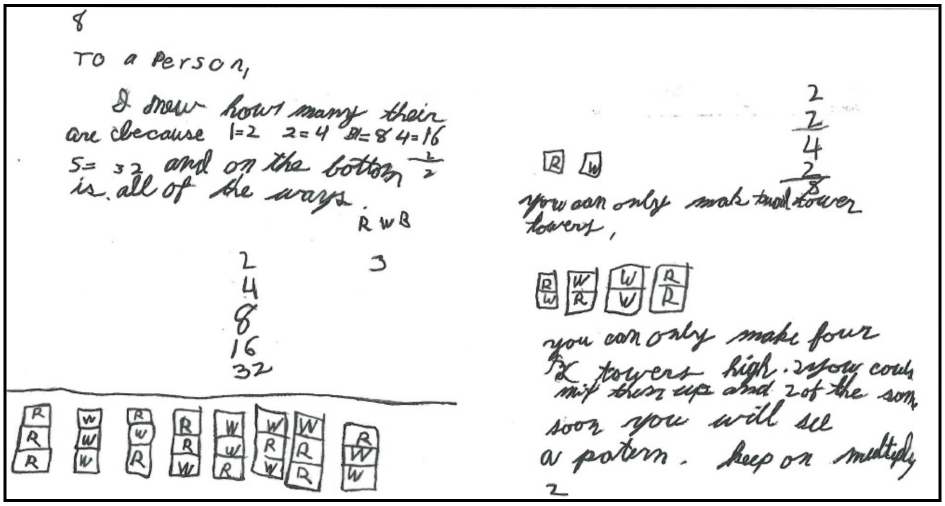

Figure 6. Milin's written response for October 25, 1992 assessment

Analysis of Milin's work showed that he first placed a cube of one color on top of all towers from (*n-1*) stage and then placed the cube of the second color to get all four two-tall towers. He repeated the process to get all eight three-tall towers as shown in Figure 7 below.

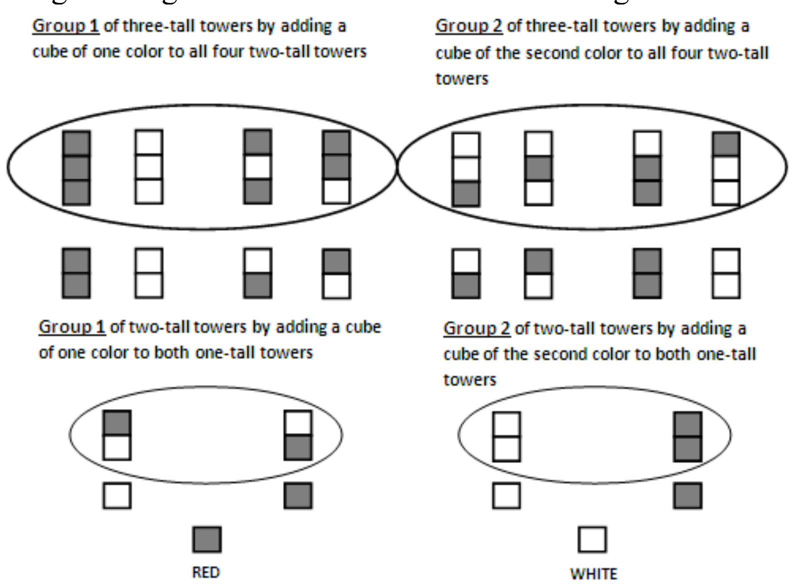

Figure 7. Milin's strategy for generating families of towers

Episode 6: February 26, 1993

Eleven months later, researchers posed a probability problem that required the building of towers of varying heights in order to determine the sample space for the experiment (Maher, Sran, & Yankelewitz, 2010b). This activity provided an opportunity for the research team to follow the durability of students' tower problem-solving ideas and simultaneously to monitor how particular strategies were shared among students. Milin successfully recalled his earlier strategy for building towers n-tall and began by sharing with his partner, Michelle. He explained by building tower models and placing the tops of the two three-tall towers (see Figure 8), and he pointed out that the smaller towers looked just like the two-tall tower. Milin then added a red cube to one tower and a yellow cube to the other (see Figure 8) as he already had before this explanation.

Figure 8. Milin's Explanation of how two-tall towers grow to two three-tall towers

Michelle indicated her understanding of the doubling pattern as she explained:

MICHELLE: You could add yellow on from there and you could also add red on. See, I understand but like its everything times two

R1: What? Tell me.

MICHELLE: Like from here from the two if you times by two you got fours

R1: Why is it that? But why is it four? I can see it is four. I can see you got eight. But can you tell me why that works?

MICHELLE: Because there is two different colors

MILIN: Yeah.

Episode 7: February 26, 1993

During Milin's explanation of his strategy for building towers of varying heights, Milin mentioned that Stephanie should also be aware of this strategy because they had shared this during the small group assessment held on March 10, 1992. This prompted R1 to invite Matt and Stephanie to Milin and Michelle's table. It was Michelle who now demonstrated her understanding of Milin's inductive argument to Matt and Stephanie. An excited Matt joined in the explanation and referred to the collection of towers as "family tree," explaining:

MATT: These are the parents-

R2: Okay.

MATT: -children, their children

Matt then shares this new understanding of the "doubling" pattern with two other students as Stephanie listens intently after she was unable to explain why the doubling pattern worked (see Figure 9).

Figure 9. Matt joins in the explanation with Michelle and then shares it with others

Episode 8: February 26, 1993

Michelle's explanation of Milin's reasoning confirmed Stephanie's conjecture that there would be 16 four-tall towers. However, while Stephanie remembered that there was a doubling pattern, it was not until this session that she demonstrated her understanding of how towers grew. As Stephanie listen to her partner, Matt's explanation, she seemed to make personal meaning as to how the doubling rule worked. An enthusiastic Stephanie eagerly shared her knowledge with her classmates (see Figure 9) referring to a "family" and its members (Maher, Sran & Yankelewitz, 2010b). She explained:

STEPHANIE: Alright, I have one red, okay? And I have a yellow, and from each of these, you can make two because all you you have to do is you add on a r..., you can add on a red to the red or a yellow to the red. And for the yellow, you can add on a red to the yellow and a yellow to the yellow, okay?
MICHELLE: So you don't have to look for duplicates.
STEPHANIE: Then each one of these has two. Like, okay if this is a family tree, thi... the mother, the parents
STUDENTS: Laughter
STEPHANIE: Have kids and then, six kids, okay, well actually, no eight kids. Then they have eight kids, and each one of them has two kids. And this one, you can add one red one yellow, one yellow one red

Figure 10. Stephanie presents her understanding of the "doubling" pattern to the entire group

Discussion

Local organizational strategies can be powerful in learning. In his early work, Milin made use of these to organize groups of towers. He began his problem solving by building random towers with the cubes by using "guess and check" methods, randomly making a new tower and then comparing it those that were already built in order to identify duplicates. He then created pairs and groups of towers that had similar properties. These groupings included opposites by color, opposites by inverting and then, staircase/elevator patterns. He discovered, however, that these strategies were no longer efficient for building taller towers. When these new organizations were inadequate to justify a complete solution, Milin developed a *family* strategy, based on his conjecture of a doubling pattern. This seemed to have triggered his finding a global organizational strategy that he referred to as a *family* (Maher, Sran & Yankelewitz, 2010a, 2010b; Sran, 2010). These organizations and strategies offered Milin important components for building a global organization that worked for towers of any height when choosing from two colors. Further, it eliminated the need of checking for duplicate towers. The progression to the *family* solution was an iterative process in which Milin revisited earlier strategies and built on and extended them.

The activity of problem solving with peers and the opportunity to share progress with researchers provided Milin with the time and resources that were needed to build his inductive argument and share it with classmates. The problem-solving investigations were integrated into regular classroom work. This suggests that there is a potential to engage students in thoughtful problem solving at an early age, providing an opportunity to build and share proof-like arguments.

Research in the field of mathematics indicates that many students struggle with justification and proof. However, in non-mathematical contexts, students are relatively strong at inferential reasoning. Our research presents two parallel lines of investigation—one focused on mathematical domains, the other focused on non-mathematical domains—in order to examine and compare the ways in which students reason in each. We report on three interrelated studies:(i) a small-scale interview study in which students were asked to sort numbers, shapes, and birds according to their characteristics;(ii) a small-scale interview study in which students were asked to determine whether various properties were true or false; and (iii) a large-scale survey to further elaborate the results from the first studies.

Justification and proof serve important roles in the field of mathematics, and consequently, there is increasing concern among mathematics educators regarding the difficulties students demonstrate in learning to reason mathematically (Healy & Hoyles, 2000; Kloosterman & Lester, 2004; Knuth et al., 2002). In non-mathematical domains (e.g., biology), however, the research is strikingly different: cognitive science research highlights considerable strength in students' causal reasoning (e.g., Gelman & Kalish, 2006; Gopnik et al., 2004). These seemingly conflicting findings serve as the driving force behind our research: why is it that students struggle to reason mathematically and yet are simultaneously skilled at reasoning outside of mathematics? In order to begin answering that question, we adopted a methodology often used in cognitive science (e.g. Kalish & Lawson, 2007) to examine students' reasoning in the mathematical domains of number and geometry. The main objective was to examine different types of inductive strategies students use in mathematical domains. Outside the mathematics classroom, children typically develop facts and ideas via empirical generalizations and causal theories (Chater & Oaksford, 2008), and students may therefore rely on and make connections to their non-mathematical ways of reasoning as they encounter ideas and problems in mathematics. This paper reports the results of the first phase of a multi-year study designed to explore the connections between students' reasoning in mathematical and non-mathematical domains.

Leveraging Inductive Reasoning

Researchers in mathematics education acknowledge the difficulties students have with formal proof (Dreyfus, 1999; Healy & Hoyles, 2000; Knuth, Choppin, & Bieda, 2009), and generally consider the inductive reasoning skills that students typically employ to interfere with their development of deductive means of reasoning and justifying. Researchers in cognitive science have found that students have difficulties *in general* with formal inference and deductive arguments, but they—unlike many mathematics educators—have continued to pursue a deeper examination of inductive inference. We agree with the latter that inductive reasoning is a powerful and useful tool, and are consequently beginning to extend cognitive science research on strategies of inductive inference to the mathematical content domains of number and geometry.

Cognitive science researchers have examined the inductive judgments people make and found that peoples' beliefs are frequently based upon category membership status, similarity, and typicality (see Feeney & Heit, 2007). For example, after being told a novel property that a robin possesses, people are more likely to extend that property to other robins than to all other birds in general. People are also more likely to extend that novel property to a blue jay than to a mouse, based upon perceptions of greater similarity between robins and blue jays than between robins and mice. In addition, people believe a robin to be a more typical bird than a penguin, and are consequently more likely to generalize from robins to all birds than from penguins to all birds (Osherson et al., 1990). In mathematics we lack a similar knowledge of students' understanding of the categories, levels of similarity between objects, and typicality of objects that may inform students' inferential reasoning. Therefore, the purpose of this course of study is to understand and map students' similarity and typicality judgments in the mathematical content domains of number and geometry.

This paper follows a three-part study design in which the results of each study were used to design and implement the following study, chaining together in such a way that the third study relied upon as well as further elaborated the results of both the first and second studies. Given this dependent relationship, as well as the quite distinct differences in methodologies and consequent analyses for each study, we outline each study and attendant results individually, focusing particularly on the ways that the studies build upon each other.

Study 1

In order to design a study that would elicit the typicality ratings and similarity relations for numbers and shapes (triangles and parallelograms), we needed to identify what features of each domain were considered relevant. When looking at triangles, for example, what do middle school students, undergraduates, and mathematics and engineering (hereafter STEM) graduate students see as important characteristics? Consequently, we designed a structured but open-ended methodology that prompted interviewees to utilize and share their own feature classifications.

Methods

We adopted the sort-re-sort procedure used by Medin et al. (1997). In one-on-one interviews, participants were presented with a set of cards that contained numbers or geometric shapes, the selections of which were based upon the varying of dimensions identified by previous research (Feldman, 2000; Miller & Gelman, 1983; see Figure 1).

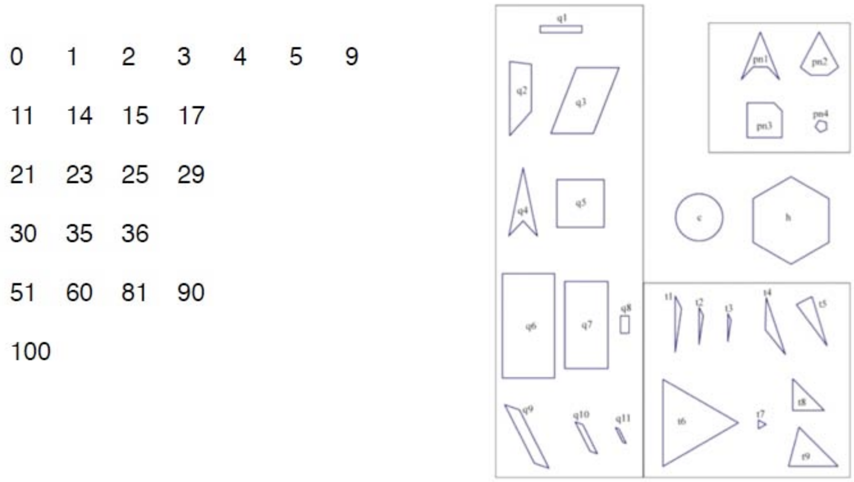

Figure 11: Number and shape cards.

Participants were asked to form groups with the cards, and then encouraged to further separate cards within those groups. Once sorting appeared to be complete, the cards were reshuffled and the participants were asked to form different groups. The sorting-re-sorting was continued until the participants had exhausted their different ways of grouping. The participants included 14 middle-school students, 14 undergraduate students (from a wide variety of majors with calculus the highest level of college mathematics completed), and 14 STEM graduate students).

Results

The results were striking because the different populations (middle-school students, undergraduates, and STEM graduate students) were not particularly different in their sorting and their sorting rationale. The following tables (see Tables 1 and 2) contain a list of several features used in the sorting task, along with the percentage of use by each population. In presenting the results, only those features noticed by at least 50% or more of the middle school students are included as that population is the primary focus of our research.

Table 4: Number Features.

Features	Middle Schoolers	Undergraduates	STEM Grads
Multiples	86%	93%	93%
Parity	79%	93%	87%
Prime	50%	71%	80%
Value of Digit	50%	29%	47%

In the domain of number, participants in all three groups were likely to remark upon features such as number parity, whether or not a number was prime, and the multiples of numbers. Comparing across populations (and not included in the table), the STEM graduate students were most likely to notice square numbers (53%), undergraduate students were most likely to remark upon shared digits between numbers (43%), and middle school students were most likely to mention factors of numbers (21%). Interestingly, in general undergraduate students did not appear, as might be expected, to be very different in their sorting than the middle school students—perhaps an indication that the salience of particular features seems to have a complex relationship with mathematics expertise.

The same trend appeared in the domain of geometry, such that there was not a clearly defined trajectory from middle school novices to STEM experts. Table 2 contains a list of the geometric features used to sort by at least 50% of the middle-schoolers, along with what percentage of each population sorted by that feature.

Table 5: Shape Features.

Features	Middle Schoolers	Undergraduates	STEM Grads
# of Sides	100%	100%	100%
Size	78%	85%	100%
Shape	64%	78%	93%
Angles	64%	85%	80%
Similar	50%	43%	40%

Once again, there were some particularly interesting similarities between the three groups, particularly that all of the participants remarked upon the number of sides. Middle school students, undergraduates, and STEM graduate students were all relatively likely to remark upon the size or shape of a geometric object. In addition, these two features are the only two that showed a progression from middle school students to undergraduates to STEM graduates. Other features was more erratically patterned. For example, 20% of the middle school students and about 50% of the STEM graduate students remarked upon the regularity of shapes, but none of the undergraduates sorted by regularity. In contrast, the similarity of shapes (i.e., the size and shape of geometric objects) was noted the more by middle school students than either undergraduates or STEM graduates, with the latter being least likely to use the feature to sort. (For more detail on Study 1, see Knuth et al., In press.)

Study 2

The results from Study 1 provided insight into the features of mathematical objects that are salient to middle school students, undergraduates, and STEM graduate students. Study 1 reveals something of the structure of students' representations of the domains of number and shape. Study 2 went on to explore whether this structure influences reasoning and proof strategies.

Methods

We designed a two-part semi-structured interview protocol in which we presented participants with both specific and general propositions and then asked them to determine whether the propositions were always true (see Figure 2).

Eric came up with a new mathematical property. He thinks this property is true for every whole number.

Eric's property:
First, pick any whole number.
Second, add this number to the number before it and the number after it.
Your answer will always equal 3 times the number you started with.

Lewis came up with a new mathematical property. He thinks this property is true for every triangle.

Lewis's property:
For any triangle, two of the sides added together are longer than the third side.

Figure 12: Specific propositions.

If students used examples in attempting to determine the truth of a proposition, they were asked about their example choices, including their judgment of the similarity and typicality of each example. For the number proposition above, for example, one participant used the numbers 4, 6, 8, and 5 to check the proposition's validity. When the participant had determined to her satisfaction that the proposition was true, she was then asked whether any of the numbers were unusual or typical. The final series of questions for each proposition asked the participant to share their beliefs about the similarity of the numbers and shapes they tested:

> *Interviewer:* "So are all these numbers similar to each other or different than each other?"
>
> *Participant:* "Well, I guess I think of 4, 6, and 8 as similar. Because they're all even. And I think of 5 as different because it's an odd number."

Next, the participants were presented with general propositions (see Figure 3, as an example) and asked to supply examples that varied in typicality and similarity. In particular, participants were

Maria came up with a new mathematical property. She thinks this property is true for every triangle.

****

If someone asked you to pick a very **typical** triangle to test if this property is true, what triangle would you pick?

If someone asked you to pick a third triangle that is very **different** than your first one, what triangle would you pick?

If someone asked you to pick another triangle to test that is very **similar** to your first one, what triangle would you pick?

Figure 13: General proposition.

asked to generate three different examples to test: a typical example, an example similar to that typical example, and an example different from that typical example.

The participants included 14 undergraduate students (not discussed in this paper) and 20 middle-school students. Further details about the methodology and results from the middle school students' responses to specific propositions are presented in Cooper et al. (2011).

Results and Discussion

Results from Part 2 suggest that the vast majority of middle-school students can use example-based reasoning as a method of proof, that more examples tended to be more convincing than few examples, and that the greater the variety of examples, the more convincing. Variety, here, seems to validate the numbers and shapes we used in Study 1, as students talked about varying numbers and shapes along the very dimensions we tried to systematically represent in the sorting task. Particularly, students frequently reported using typicality and similarity judgments to inform their selection of items as they tested examples. Importantly, students who discovered deductive proofs were less likely to vary examples overall, but on the problems where they did vary examples, they reported using variations in typicality and similarity in an intentional manner. While students who did not discover deductive proofs tested the greatest variety of examples, their variation was not intentional.

Students frequently referenced their everyday experiences—both inside and outside the mathematics classroom—during the interviews. For example, a respondent who talks about squares being typical because all the corners have 90 degree angles is quite different from the respondent who declared a tall rectangle to be typical because it was a common skyscraper shape. This result prompted us to reconsider the idea that typicality is a singular construct, and instead reframe typicality as context-relevant. In addition, as was also found in Study 1 with the non-linear trajectories of participants attending to particular mathematical features, in Study 2 middle school students' typicality judgments for number and geometry categories did not always correspond to expert-based dimensions. In particular, we became interested in how the student-based notions of typicality contrast with expert-based knowledge relating to special mathematical properties.

For instance, in a mathematical contexts, for the purposes of justification, experts may consider mathematically-special numbers like 0 and 1 to be highly unusual or atypical – mathematical properties that hold for these numbers may not be generalizable, and these numbers may be useful to employ in the search for counterexamples. However, in terms of numbers seen in everyday life, these numbers are very typical or common. The analysis of examples given by students and their associated typicality comments led us to tentatively map numbers and shapes by their everyday usual-ness (student typicality) and by their mathematical

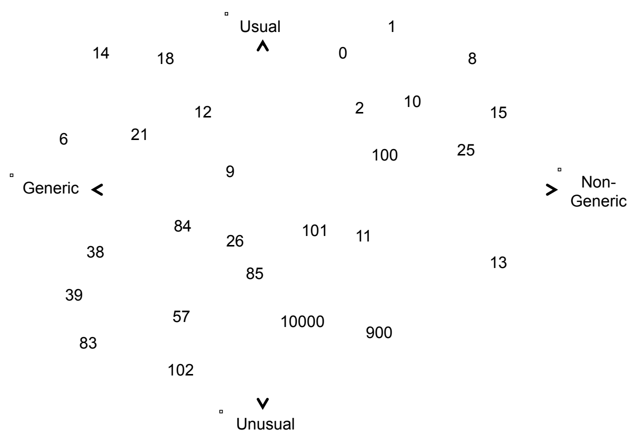

Figure 14: Everyday versus generic number placement.

generic-ness (mathematical typicality, where non-generic indicates a high presence of mathematical properties, such as prime-ness in numbers or congruence in shapes). Figure 4 illustrates our placement of numbers according to these two dimensions.

Study 3

Given the intriguing results from Studies 1 and 2, our next step was to administer a survey to a large enough number of middle school students to validate our results. Given the need to consider the importance of context, we determined that cuing the students to the context of "math class" versus "everyday life" was a necessary nuance. That is, we wanted to find out if students consider the expert-based generic-ness dimension of number and shape typicality if sufficiently prompted to consider these objects in a mathematical context.

Methods

We designed a 7-point Likert-scale survey where students rated the typicality of items in three different mathematical domains (numbers, triangles, parallelograms) and three different contextual cues (neutral, mathematical, everyday) (see Table 3). Through careful variance of features, items covered a wide gamut of types—in triangle, for example, we included isosceles, equilateral, and scalene, and varied both the size and the orientation of the shape (some shapes had a side parallel to the bottom of the survey page, while others did not). Additionally, we always placed the neutral cues first, but otherwise varied the order of the cues and domains.

Table 3: Stimuli prompts in the number domain.

	Neutral Context	Mathematical Context	Everyday Context
Section Prompt	Now we want you to think about how typical different numbers are.	Now we want you to think about mathematical properties – that is, the kinds of things you learn about in math class.	Now we want you to think about numbers you see in everyday life outside of school, for example, around your house, in stores, or outside.
Individual Item Wording	Think of numbers. How typical is this number? [item displayed]	Imagine that we learned a new mathematical property that was true of this number. How likely is it that the property will be true of most other numbers? [item displayed]	How typical is this number of those you see in your everyday life? [item displayed]

A total of 474 middle school students, drawn from a suburban middle school in a Midwestern state, completed the survey. Students were distributed across grades 6 (144 students), 7 (160 students), and 8 (163 students), and mathematics classes used reform texts.

Results

Using the findings of Study 1 and Study 2, we identified a number of mathematical and non-mathematical properties that we hypothesized students may attend to in their typicality rankings (see Figure 5). We computed the mean typicality rating for items falling into each of these categories, depending on whether the item was presented in a mathematical or everyday context. The results suggest that while both mathematical (generic-ness) and non-mathematical (common-ness) properties can influence typicality ratings, the everyday notion of typicality is most salient to middle school students. The results also indicate that contextual cues do not significantly influence students' typicality judgments, and that even cueing the context "mathematics classroom" did not increase the likelihood that students would attend to particular mathematical properties.

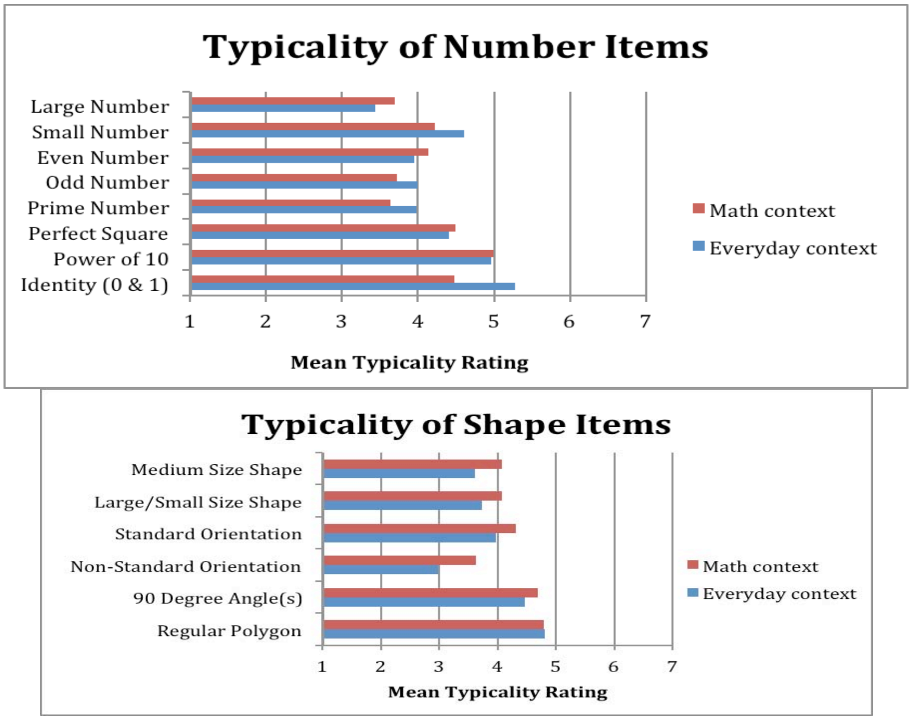

Figure 15: Mean typicality ratings for number and shape items.

Conclusion

Study 1 resulted in an identification of various sorting features of mathematical objects noticed by middle school students, undergraduates, and STEM graduate students, and furthermore, suggested that patterns across the three participant groups are not simple. In the domains of both number and geometry, an increase of mathematical expertise does not necessarily manifest itself in a higher likelihood of noticing particular features, and the three groups varied in the features to which they attended. The results of Study 2 suggest that typicality and similarity judgments may play a role in inductive and deductive reasoning, and that participants believed that varying the typicality and similarity of examples is a good strategy for testing propositions in both number and shape. In Study 3, the survey validated our initial smaller-scale interview studies, providing more confidence in our student typicality (usual-ness) identification of specific numbers and shapes. In the next phase of our work, we are further investigating the relationship between similarity/typicality and the nature of the empirical arguments student generate.

We believe that inferential reasoning can be leveraged to support the development of deductive reasoning, as it seems that applying strategies frequently used for the domain of living things—that is, thinking of examples, typicality, and similarity—can support the development of more sophisticated ways of reasoning in mathematics. Our research highlights the need to more closely and systematically examine inferential reasoning in mathematics, and instead of viewing students' use of examples as inappropriate or limiting, we view such use as a potential means of improving students' abilities to reason deductively. The importance of proof in mathematics, and the struggle of most students to justify and reason deductively, suggests that this examination is of paramount importance, and our research opens a new—and hopeful—line of study.

QUANTIFYING INSTRUCTIONAL FOCUS ON PROCEDURAL UNDERSTANDING IN ALGEBRA: A DIGITAL OBSERVATION PROTOCOL

Jon F. Hasenbank
University of Wisconsin, La Crosse
hasenban.jon@uwlax.edu

Ted Hodgson
Northern Kentucky University

Jennifer Kosiak
University of Wisconsin, La Crosse

We present a new digital observation protocol that captures the moment-by-moment emphasis of a lesson along a set of customizable dimensions. The result is a time-series graph showing the lesson progression, including the total amount of time allocated to each dimension during instruction. We present the results of a small scale study to illustrate how the tool may be used to characterize instruction along dimensions relevant to the newly released Common Core State Standards for Mathematics. We conclude by outlining our plans for using this tool to study the relationship between procedural understanding instruction and student achievement levels.

The call for mathematical understanding has been voiced by several prominent groups in the past 10 years (e.g., The National Council of Teachers of Mathematics, 2000; the National Mathematics Advisory Panel, 2008; and the National Research Council, 2001). More recently, the introduction of the Common Core State Standards (CCSS) for Mathematics makes the case for understanding succinctly while simultaneously raising important questions about implementation:

> These Standards define what students should understand and be able to do in their study of mathematics. Asking a student to understand something means asking a teacher to assess whether the student has understood it. *But what does mathematical understanding look like?* One hallmark of mathematical understanding is the ability to justify, in a way appropriate to the student's mathematical maturity, *why* a particular mathematical statement is true or where a mathematical rule comes from. There is a world of difference between a student who can summon a mnemonic device to expand a product such as $(a + b)(x + y)$ and a student who can explain where the mnemonic comes from. The student who can explain the rule understands the mathematics, and may have a better chance to succeed at a less familiar task such as expanding $(a + b + c)(x + y)$. Mathematical understanding and procedural skill are equally important, and both are assessable using mathematical tasks of sufficient richness (CCSS, 2010, p. 4; emphasis added).

Our work emerges from the belief that while the CCSS and other documents advocate an instructional focus on understanding, the construct of "teaching for understanding" is rarely defined in a concrete and useful way. What constitutes teaching for understanding, and how are teachers to achieve this goal in the classroom? The research described in this paper is part of an ongoing effort to operationalize the process of teaching for understanding and assess its utilization in the classroom. To address the latter objective, we have developed a time-sensitive digital observation tool, which we describe in detail in this paper. We conclude with a brief review of the results obtained thus far and future efforts to confirm (or refute) the educational benefits of teaching for understanding.

Operationalizing Understanding

Resources for refocusing instruction on teaching for understanding (e.g., Blythe, 1998; Wiggins & McTighe, 2001) provide general strategies for teachers but often lack the content specificity needed to significantly reform high school mathematics instruction. Reflecting on this need and on the qualitative differences between "A-students" and "C-students," Burke (2001) developed a framework of mathematical "literacies" that characterize expert performance in algebra. This framework was eventually incorporated into NCTM's *Navigating through Algebra in 9-12* (Burke, Erickson, Lott, & Obert, 2001) and serves as the theoretical basis of our work. As Table 1 illustrates, Burke's original framework was stated in terms of student competencies, which we have translated into student-centered (and teacher-centered) questions.

Burke's Procedural Literacies	*Student-Centered Framework Questions*
The student understands the overall goal of the procedure and knows how to predict or estimate the outcome.	1a. What is the goal of the procedure? 1b. What sort of answer should I expect?
The student understands how to carry out the procedure and knows alternative methods and representations of the procedure.	2a. How do I execute the procedure? 2b. What are some other procedures I could use instead?
The student understands and can communicate to others why the procedure is effective and leads to valid results.	3. Why is the procedure effective and valid?
The student understands how to evaluate the results of the procedure by invoking connections with a context, alternative procedures, or other mathematical ideas.	4. What connections or contextual features could I use to verify my answer?
The student understands and uses mathematical reasoning to assess the relative efficiency and accuracy of the procedure compared with alternative methods that might have been used.	5. What do I look for to decide if this the best procedure to use?
The student understands why the procedure empowers her or him as a mathematical problem solver.	6. What can I use this procedure to do?

Table 1. Burke's Literacies and the FPU Questions

These student-centered questions (heretofore, the Framework for Procedural Understanding or FPU) are based upon the premise that the dichotomy between procedural skill and conceptual understanding is a false one (Star, 2005; Wu, 1999). Indeed, recent models of mathematical knowledge have challenged the assertion that conceptual knowledge is deep, meaningful, and connected, whereas procedural knowledge is shallow and rote (Baroody, Feil, & Johnson, 2007; Star, 2007, 2005). According to these models, mathematical procedures and mathematical concepts can each be known in either a shallow or deep way; it is the number of connections that defines how deeply one knows, and hence how well one understands, a given procedure or concept (Star, 2005; Hiebert & Handa, 2004; Skemp, 1978). Figure 1 illustrates this conceptualization, depicting two independent dimensions of growth that are applicable to the learning process – depth and practice (Hasenbank, 2006). The illustration is meant to apply equally well for procedural and conceptual knowledge.

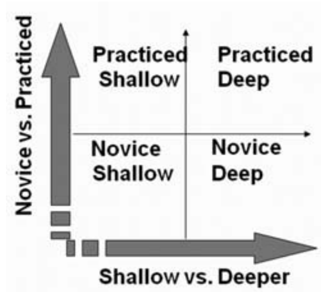

Figure 1. Levels of Conceptual and Procedural Knowledge

The FPU provides a working definition for what the CCSS has termed "mathematical proficiency." Collectively, the questions that constitute the FPU are meant to focus instruction, assessment, and reflective practice on important habits of mind (Driscoll, 1999) that lead to more robust mathematical understanding. In our prior work, we have often illustrated the alignment of the FPU with the recommendations of the "Adding It Up" report (National Research Council, 2001), the Principles and Standards for School Mathematics (NCTM, 2000), and the National Mathematics Advisory Panel report (2008). Given that the CCSS (2010) build upon and in many ways subsume the aforementioned documents, it is not surprising that FPU is also well-aligned with the CCSS. The CCSS Standards for Mathematical Practice, for instance, emphasize that students are to make sense of problems and persevere in solving them:

> Mathematically proficient students start by explaining to themselves the meaning of a problem and looking for entry points to its solution. They analyze givens, constraints, relationships, and **goals.** They make conjectures about the form and meaning of the solution and plan a solution pathway rather than simply jumping into a solution attempt. ... Mathematically proficient students check their answers to problems using a different method, and they continually ask themselves, "Does this make sense?" They can understand the approaches of others to solving complex problems and identify correspondences between different approaches. (CCSS, 2010; from the Introduction, emphasis added)

Likewise, instruction that employs the FPU encourages students to identify the goal of the algebraic procedure (question 1a), identify or estimate the expected answer (question 1b), seek and compare the relative efficiency of alternative procedures or strategies to complete each task (questions 2b and 5), and verify one's solution (question 4). Given national efforts to implement the recommendations of the CCSS, therefore, a focus on FPU (or any effort to establish the impact of CCSS-recommended practices) is particularly timely.

Characterizing Instruction

In a series of studies, we have trained teachers to utilize questioning techniques, classroom activities, and a wide range of assessments that incorporate the FPU, and we have evaluated its impact on student learning. In these studies, we observed statistically significant gains favoring students in the "treatment" condition. Here, we will provide just a brief overview of the results and refer the interested reader to the cited papers if more details are required. In our first study, we found that college algebra students scored significantly higher on a test of procedural understanding versus a matched comparison group (Hasenbank, 2006; Hasenbank and Hodgson, 2007). In a second study, we focused on high school algebra classrooms in southwestern Wisconsin and observed significantly greater gains in procedural skill versus a matched comparison group over a one year period (Hasenbank & Kosiak, 2008; 2010).

One outgrowth of these efforts to assess the impact of FPU-related practices is the need to establish fidelity of implementation. In our second research study, for instance, we observed that teachers implemented the FPU in different ways and to differing degrees. To quantify these differences, we employed a digital classroom observation tool (described in greater detail below) which provided concrete evidence of the variability we observed in teacher practice. The graphs in Figure 2, for instance, illustrate the contrast between two algebra lessons presented by two different teachers. The vertical scale records a timestamp, while the horizontal categories represent the instructional focus at that moment in time. The eight categories represent the eight dimensions of the Framework (note that the labels {1a, 1b, 2a, 2c, 3, 4, 5, 6} have been mapped to {1, 2, 3, ... 8}).

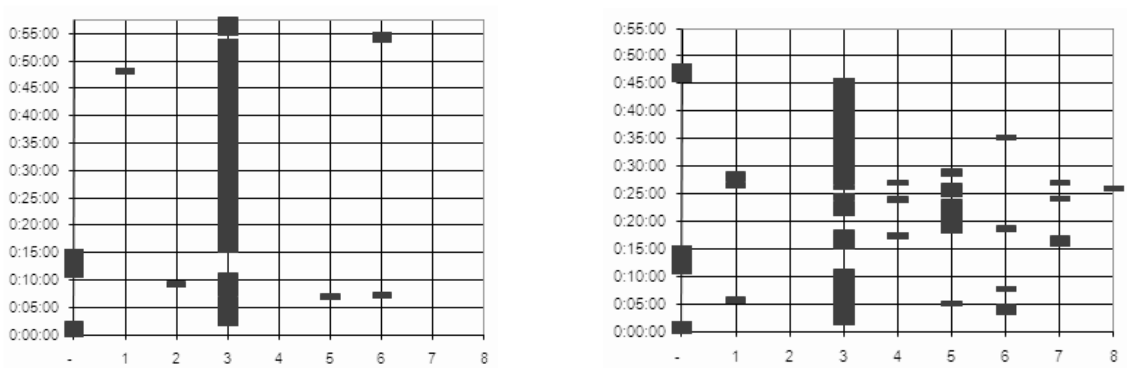

Figure 2. Lesson Progression for Two Different Classroom Episodes

It is clear that both teachers placed a significant emphasis (85% and 61% of class time, respectively) on category 3 (performing the procedure), but the teacher on the right also integrated other aspects of the FPU into the lesson. For instance, she spent nearly 6 minutes, or about 12% of the lesson, on discussions categorized as ‘category 5 - why the procedure works.’ We also categorized another 9% of her lesson on other FPU categories, with discussing the merits of various procedures and questioning the reasonableness of the results making up the next two largest components (4% and 3% of the lesson, respectively). This variability in classroom practice among teachers who were explicitly trained to implement FPU-oriented instruction leads naturally to the questions driving our on-going research agenda. Specifically, “To what extent do algebra teachers already focus on FPU-oriented principles in their daily lessons?” and “Is there a relationship between the instructional focus within an algebra classroom and student performance/achievement?”

Digital Classroom Observation Protocol

While there were a number of written observation protocols in existence that captured information similar to the digital tool we set out to create, none captured and summarized the moment-by-moment focus of instruction on understanding in real time in a format that permitted direct comparisons between observations. Many existing observation protocols (e.g., the Praxis III: Classroom Performance Assessments, ETS, 1993; the Reformed Teaching Observation Protocol, Arizona State University, 2000; or the Inside the Classroom Observation and Analytic Protocol, Horizon Research, 2000) take the form of a written observation protocol that provides space for noting the time, recording comments, and selecting a category or rating that reflects the nature of the entire classroom episode.

Our digital observation instrument improves on those protocols by recording a timestamp whenever the observer selects a different primary or secondary code or records a typed comment. For the purposes of our research, we use the eight dimensions of the FPU (plus “conceptual” and “other”) as our primary codes (see Figure 3). During an observation, the observer switches between the appropriate code categories and enters qualitative descriptions where desired. By recording a timestamp whenever a change is made, the instrument captures the researchers’ perception of the lesson progression over time.

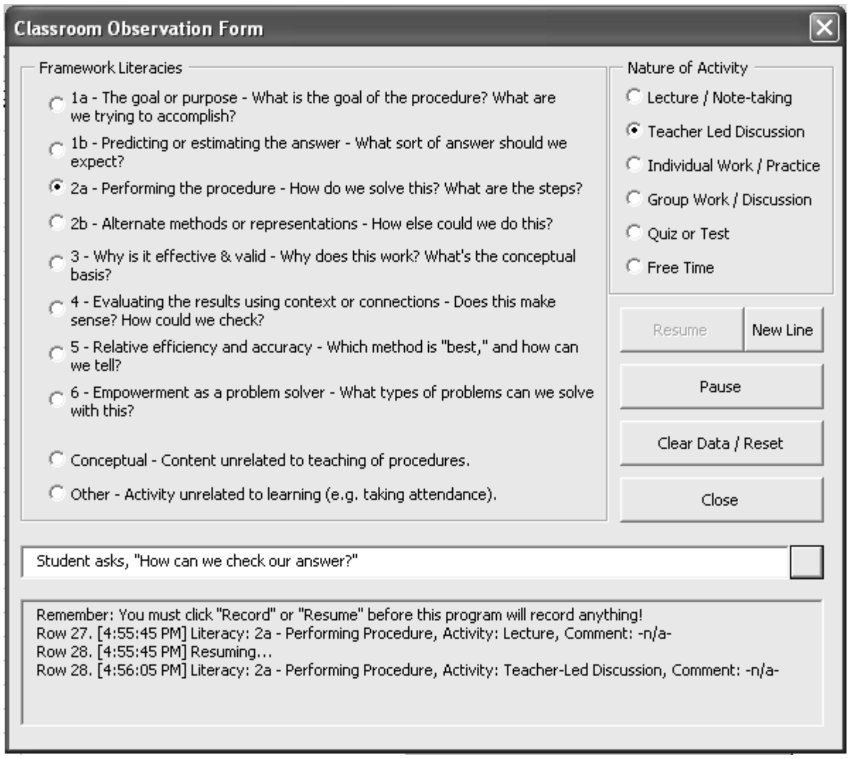

Figure 3. User Interface for the Digital Classroom Observation Form

The observation instrument also generates two visual displays of the lesson progression (see Figure 4). On the left, we see a graph of the chronological progression of the lesson showing how the categories (horizontal axis) shift over time (vertical axis). On the right is a simple bar graph showing the relative frequency distribution for the primary categories. This digital observational protocol allows researchers to characterize the extent to which instruction focuses on procedural understanding and each component of the FPU.

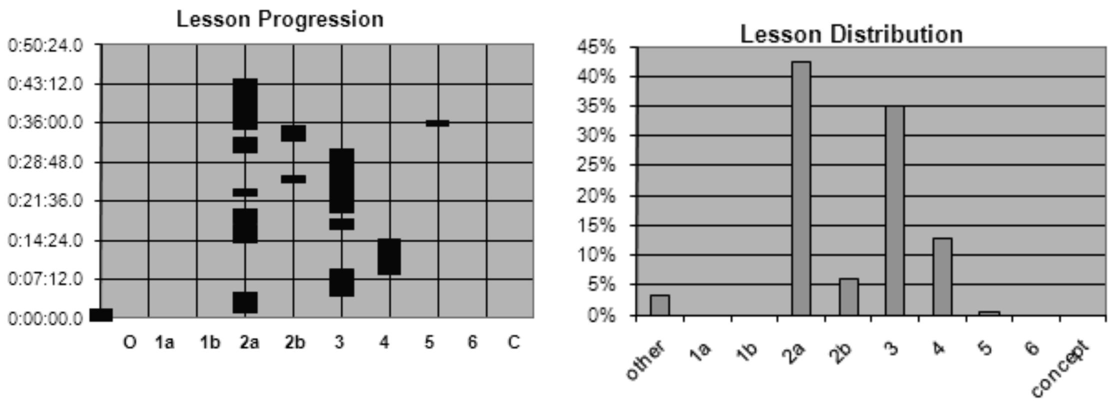

Figure 4. Visual Displays of Lesson Progression

Inter-rater Reliability

Two independent observations may be merged to allow for both visual and numerical assessment of inter-rater reliability. The software discretizes the data by sampling at fixed time intervals (e.g., one sample every five seconds) and generates a table reflecting the pair-wise associations of the primary codes assigned by the two observers (Figure 5). If the observers were in agreement at each discretized moment, all entries would appear on the main diagonal of the table. Summing the entries along the main diagonal gives the percentage of discretized intervals on which the researchers' codes agreed (72% in the example shown). Examining the off-diagonal elements allows us to identify the most common areas of disagreement (e.g., code 5 with code 3 occurred 7% of the time in our example), which can be cross-referenced with the chronological progression plot and the observers' comments for clarification. The code-pairs are used to compute Cohen's *kappa*, which provides a statistical representation of the extent of the observers' agreement beyond that expected by chance alone (Agresti, 1990).

Results on the Nature of Algebra Instruction

Our observations of the teachers participating in our professional development program can be viewed as a snapshot into the nature of algebra instruction in Wisconsin. These teachers were trained to cultivate classroom norms that promote understanding using the FPU as a guide. In that study, five algebra teacher participants from rural and suburban Wisconsin were observed a total of 21 times using the digital observation instrument. The combined results are displayed in table 2 below. We note teachers devoted an average of nearly 37 minutes per hour of instruction-time on procedural skill (item 2a of the FPU), with a range from as little as 32 minutes up to about 48 minutes per hour of instructional time. By comparison, these same teachers spent an average of only 12 minutes on the non-routine aspects of the FPU, with times ranging from 6 to 20 minutes per hour of instruction-time.

We believe these results demonstrate the utility of our observation protocol; we are able to quantify the focus of instruction in a manner that allows for rigorous statistical analysis. It also affords us with a critical tool for answering the question: how much FPU-oriented focus is enough?

Category	Mean (Median) in Minutes Per Hour	S.D. (Range)	Min & Max
Procedural Skill	36.9 (34.8)	6.28 (16.0)	31.8 to 47.8
Procedural Understanding	12.4 (13.1)	5.13 (13.5)	6.3 to 19.8
Non-Framework categories	10.7 (11.6)	4.78 (10.5)	5.7 to 16.1

Table 2. Distribution of Time across FPU Categories

Discussion and Future Directions

In summary, our digital observation tool allows researchers to characterize the nature of instruction with a degree of precision not previously available. It should be noted that the categories used for observation are easily customized, so the tool is easily adapted to a wide variety of research areas where a predefined set of observable categories of behavior are available. Our own future plans include observational studies with high school, middle grades, and college algebra sites, through which we will attempt to correlate individual teachers' emphasis on FPU with student achievement. With the introduction and widespread adoption of the CCSS, the importance of understanding the variables associated with procedural understanding has never been higher. If indeed malleable factors such as teachers' emphasis on procedural understanding tasks are confirmed to be significant predictors of student achievement, we will have identified key focal points for professional development of teachers. We are hopeful that the data we gather will afford us a better understanding of how—and to what extent—teachers institute the mathematical practices outlined in the CCSS and as operationalized by our Framework for Procedural Understanding.

A research is reported in which we carry out an analysis of the students cognitive process, whom are asked to solve a contextualized event on systems of linear algebraic equations in the context of matter balance in situations of chemical mixtures. The cognitive analysis is founded on the theories of Conceptual Fields and Mathematics in the Sciences Context. The analysis is focused on the representations carried out by students regarding the invariants in the schemes that they build. During the students acting process emerge different types of representation which are appropriate to the context in which the research develops.

Introduction

The need for a comprehensive training on the student, has led the Red Internacional de Investigación en Matemática en el Contexto de las Ciencias (MaCoCiencias) to perform research of cognitive type that revolves, among others, around the analysis of the cognitive processes of students for the knowledge construction of various sciences who are linked. Addressing science events such as a chemical or physical system or a natural phenomena, where mathematics should be applied for their solution, is a complex task; because it is necessary to integrate the knowledge and carrying out activities of analysis for knowledge which is both explicit and implicit in the event to be addressed (Camarena, 2000: 27-32), playing an important role in the representations which can be formulated about the events to be dealt with, in order to promote the construction of knowledge. Moreira (2002, p. 37) assumes that we do not apprehend the world directly, but we do it from the representations of the world that we build in our minds.

Learning mathematics, among others, implies that the learner is able to use them to solve specific events in his area of professional and labor job (Camarena, 2000: p. 46) Thus in the knowledge construction of various related sciences, it is important to know from the cognitive point of view what happens to students when they work with contextualized mathematics.

Research Problem

There are many actions that favor the knowledge construction on students, among them stands the learning and teaching activities with contextualized mathematics. The research that is carried out regarding the cognitive process of students provides a guideline for the design and redesign of these didactic activities in students at university and technical programs. The research reported makes use of the conceptual fields by Vergnaud for the cognitive analysis.

Thus, the research problem deals with the issues of how the cognitive processes of students is carry out when they are faced with contextualized events of Mathematics in Context, from the perspective conceptual fields by Vergnaud. The *research objective* seeks to analyze the cognitive process of a students group by means of analyzing the representations they make about the invariants in the schemes they build when they address the learning activities associated with contextualized events where systems of algebraic equations are linked to balance of matter; that is to say the events being addressed deal with mixing chemical solutions.

Theoretical Frameworks

Mathematics in the Sciences Context

The theory of Mathematics in the Sciences Context (Camarena, 2009: 14-25, 2000: 1-70) has been developed since 1982 through the research at Instituto Politécnico Nacional of Mexico. The theory of Mathematics in the Sciences Context reflects upon the relationship that should exist between mathematics and the sciences that require it, between mathematics and everyday life situations as well as its relationship to future professional and labor activities.

The educational philosophic assumption of this theory is that the student is trained to transfer mathematics knowledge to the areas which require it, so that they develop competences for their working and professional life, because it aims at contributing to the comprehensive training of the student and to build mathematics for life (Camarena, 2009: 14-25, 2000: 1-70).

The theory of Mathematics in the Sciences Context deals with the problem of learning and teaching of mathematics at university level programs where mathematics is not a goal in itself but a tool to support sciences and a subject that develops the students thinking skills. To this end, the theory conceives the process of learning and teaching as a system with five phases: curricular, cognitive, didactic, epistemological and teachers training, moreover, social, economical, political and human relations aspects are included in the learning environment (Camarena, 2000: p. 12). All the phases are necessary to ensure the completion of the philosophical assumption posed, moreover, all stages are interrelated among them, and none of them is unrelated to the others. As a theory, in each of the phases a theoretical methodology is included, in accordance with the paradigms upon which it is based, which serve as a guide for the steps of curricular design, the didactics to be followed is described, the cognitive functioning of students is explained and epistemological elements are provided on mathematical knowledge relating to the activities of professionals, among others.

The cognitive analysis addressed in this research directly affects the cognitive phase of the theory, where a contextualized mathematical concept acquires sense by means of the activities of the context itself, because the concepts are not isolated, they are constituted as a network and they bear a relationships among them (Camarena, 2000: p. 54). Therefore, for the cognitive analysis it is important to set the contextualized events and define from them the learning activities that lead to the knowledge construction, both of the concepts of each science involved in the event and the linkages between them, stages 4 and 9 of the didactic strategy of Mathematics in Context, shown in the following paragraph, a situation that is consistent with the theory of Conceptual Fields by Vergnaud. Thus, the didactic phase is the means by which cognitive processes are achieved; the didactic phase possesses a teaching strategy that supports the development of competencies in students within the learning environment, which is called Mathematics in Context (Camarena, 2000: 1-70).

With Mathematics in Context the student works with contextualized mathematics in the areas of knowledge of his future professional subject matter, with daily life activities and with labor and professional activities, all that through contextualized events, which can be problems or projects. In general speaking of Mathematics in Context is to develop the mathematical theory to the needs and rhythms that dictate the courses of engineering. Mathematics in Context includes 9 stages, which are developed in the learning environment in teams of three students: academic leaders, emotional leader, work leader.

Stages of Mathematics in Context: 1.- Identify contextualized events to develop the competencies being questioned. 2. Establish the event of the context. 3. Identify the variables and constants of the event. 4. Include the mathematical topics and concepts necessary for development of the mathematical model and its solution. 5. Determine the mathematical model.

6. Give the mathematical solution of the event. 7. Determine the solution required by the event in the context disciplines. 8. Interpret the solution in the event terms and the context disciplines. 9. Present the descontextualized mathematics in the classroom.

Mathematics in Context acts as didactic strategy and allow following a methodical process to contextualize mathematics through stages 2, 3, 5, 6, 7 and 8, thereby linking mathematics with other sciences of professional majors and technical programs being treated. The type of contextualized event to be chosen should have historical background, that is, it must have been previously worked upon by a teachers group in order to identify the type of components of the competencies that come into play as well as the type-questions that the students made at the time to address the events, among others. The success of the contextualized event in order for it to develop skills in students has to do with the adequate selection and with the guidance of the teacher at the time the students are solving the event.

Conceptual Field.

The theory of conceptual Fields deals with the formation of mathematical concepts from a psychological and didactic approach, which leads us to consider the learning of a concept as the set of "problem situations", which constitute the reference of their different properties and the set of schemes brought into action by the subjects involved in those problem situations (Vergnaud, 1996: p.145). The sense of the mathematical concept is acquired through the schemes evocated by the individual subject to solve a problem situation.

Vergnaud (1991: p.147) defines Conceptual Fields as "a set of problem situations, concepts, invariants, schemes and operations of thought that are related to each other for a specific area of knowledge". The theory of Conceptual Fields allows the cognitive analysis in the problem situations proposed to the students through the analysis of the conceptual difficulties, the repertoire of available procedures and possible forms of representation.

From the perspective of the theory of Conceptual Fields understanding of the student's action relative to the concepts involved and the structure of systems of linear algebraic equations in the context of a phenomenon of balance of matter, focuses on studying some aspects of the operations of thought which make the invariants in the schemes constructed by students, which directly or indirectly impact on knowledge about this mathematical structure being immersed in a problem situation where the linking of two contexts take place: mathematics and chemistry.

For representations which one of the thinking operations, Vergnaud mentions that the students transform an action on the mathematical object, establishing control by himself through the relationship and classifications in his reality, in such way that invariants arise in the knowledge development, in this way the representations for Vergnaud are tools, whichever notation or sign or set of symbols.

To finish with this section it is important to mention that the "problem situations" referred to in the theoretical framework by Vergnaud correspond to the "contextualized events" and the "learning activities" proposed by the theory of Mathematics in the Sciences Context.

Method

The methodology to carry out the students cognitive process analysis form the conceptual content of systems of linear algebraic equations in the context of matter balance involves the following three blocks: Contextualization of systems of linear algebraic equations in the matter balance. Determination of the learning activities to be applied to the students group. Analysis of the students cognitive process through the thinking operations they make upon the invariants in the schemes they construct. The last one is the results and their discussion.

The Sample

Being a qualitative analysis, we worked with a group of two students in the first quarter of the Technician in Food Technology program, who are currently enrolled in a mathematics course that includes the topic of systems of linear algebraic equations as well as a chemistry course which addresses the topic of balance of matter by mixing chemical solutions, both courses are not related in a curricular way. The activities are carried out by students in the chemistry laboratory, in different sessions, covering twelve hours.

Observation Instruments

The data collection from the cognitive process is made by obtaining written and film productions that help to refute or confirm the analysis conducted with the written information. The analysis is qualitative focusing on the thinking operations that they perform on the invariant patterns that build in their cognitive processes in the activities of contextualized event.

Development of Research

First block, contextualized event students are to face is contextualized, which is a phenomenon that recurrently appears in specific operations in the area of professional and labor training of the technician in food. It *says:* We have *100 ml of sugar solution to 60% and 100 ml of sugar solution to 35%. From these solutions it is desired to obtain 100 ml of a sugar solution to 50%.*

The contextualization stages described in the theoretical framework, which are immersed in the didactic strategy of Mathematics in Context, is the methodological process that is used for the systems of linear algebraic equations contextualized in the matter balance, generally in contextualized events of mixing of solutions.

In the didactic phase of Mathematics in the Sciences Context, contextualization is set by the teacher prior to implementing the didactic strategy of Mathematics in Context, because this contextualizing provides him with elements for the learning activities design for 4 and 9 strategy stages, similarly, to take time, see the necessities of the cognitive infrastructure and consider the possible paths of solution. Also, it allows determining the mathematical concepts and of the context (chemistry) that are present in the event, establishing the relationship between concepts that belong two different areas of knowledge and observing the close relationship between them. In terms of Vergnaud, the concepts and invariants to which the student must converge for the construction of knowledge are identified. In relation to mathematics: The concept is “systems of linear algebraic equations” and the invariants are mathematical concepts such as algebraic equation, linear algebraic equation, systems of equations and solution methods. In relation to the context: The concept is matter balance and the invariants are inherent concepts such as concentrations management, visualization of the phenomenon as a system with inputs and outputs, mixing substances to obtain a desired concentration and concentration measurements. The schemes and operations of the invariants mediate the action over reality, as well as the organization forms and structuring of the different concepts of interest and criteria for meanings acquisition.

From the contextualization of the first methodological block derives the activities to be determined in the ***second block,*** which are shown in table 1.

The learning activities objective is that the student analyzes the linear behavior by means of the obtaining of concentrations and volumes combinations, each one separately, to later on confront him with the idea of managing the two variables simultaneously, and the pursuit of the mathematical model which represents the context event, see table 1.

CONTEXTUALIZED EVENT	
We have 100 ml of sugar solution to 60% and 100 ml of sugar solution to 35%. From these solutions it is desired to obtain 100 ml of a sugar solution to 50%.	
LEARNING ACTIVITIES	**PURPOSES**
Activity 1. To mix the two chemical solutions in order to obtain as a result 100 ml of solution, do not consider the concentration of the solution only the volume.	To mix chemical solutions, from their volume.
Activity 2. To mix the two chemical solutions in order to obtain as a result a solution with a sugar concentration to 50% (do not consider the volume of the solution only the concentration).	To mix chemical solutions, from their concentration.
Activity 3. With the given solutions, 100 ml to 35% and 100 ml to 60% carry out a mixture in order to obtain 100 ml of a new solution with a concentration to 50%.	To mix solutions considering both volume and concentration.

Table 1. Contextualized event and its learning activities

As it has been mentioned, the conceptual field is constituted by problem situations (contextualized events and learning activities), concepts, invariants, schemes and thinking operations. Now it can be established conceptual field of systems of linear algebraic equations in the context of matter balance.

Results and Discussion

Third block, the behavior of students is analyzed through the operations of the invariants in the schemes they build. It must be pointed out that during activities from the contextualization of systems of linear algebraic equations with matter balance, it was detected in the students actions the recurrent use of different operations of thought, which were considered proper of the linking of two specific areas of knowledge, that is to say, they may or may not arise in other circumstances. These thought operations relate specifically to representations, for it was necessary to define a classification of the types of representations found, which is expressed below.

Propositional type representation: it is considered as the description of the event the made by the student, in the first instance, in his own language (natural language), from the cognitive point of view it is of great use to the student to understand the activity to be performed. He can use some isolated concepts of mathematics, the chemical science or other sciences, without articulating them. The overall purpose is to communicate and try to understand the event to be solved.

Non-operating figurative type representation: it is when the student perceives the information of the event but if asked to represent the situation in written form, he draws pictures, wanting to see the link between the two areas of knowledge; however, it does not allow him for a procedure of solution. When the students group understands the activities en their language they proceed to make some context area drawings (figures). However, do not shift from these figures to a written expression that enables the solution of the given event, that is to say, they still fail in linking the two areas of knowledge.

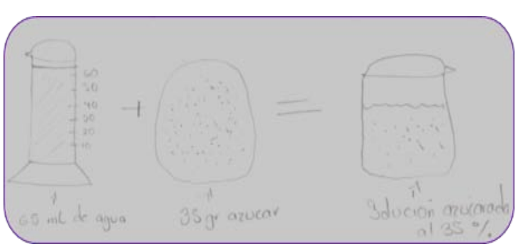
Figurative operating type representation: the student continues to make drawings but he already takes into account the numerical information, the drawing can therefore, serve as a support for the solution of the event without algorithms. Again, the experiment presented in this document, the students recurrently makes schemes (figures) representing the matter balance of the proposed activities; which allow them on the one hand to understand the variables and constants involved, and on the other hand they serve to give way to the symbolic representation that allows the event resolution. Then, at this point begins the comprehension of the link between the two knowledge areas.

Analogous type representation: the student retains the relevant information to solve the event and simplifies the information by using symbols, points, crosses, use of images. He uses the experience of having solved previous events to solve the new one, at least partially, by a very primitive process and of very local scope, that is to say, the similar events processes are considered to verify if they are helpful in solving the new event. The analogous representation can be used after the propositional and even after the non-operating figurative one and it is when the student refers to processes that appear similar to the one he faces and that can be useful for event understanding and resolution. His search for similar events allows him to support the emerging understanding of the previous representation.

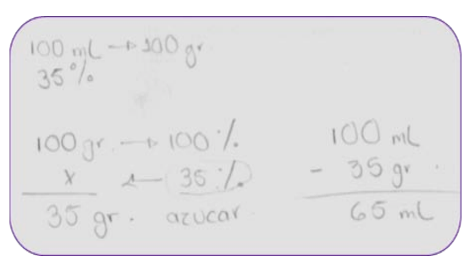
Symbolic type representation: it has been considered that these representation constitutes a means to identify more clearly the mathematical objects for the conceptualization of them and the conceptualization of context. The student translates the sentence of an event to a mathematical representation, arithmetic, algebraic, analytic or graphic, this representation is considered as an expert and allows providing the required response. It is considered that knowledge is obtained that can be used in different contexts. The students group who have gone through the previous representation, makes use of a symbolic representation (it may be graphic, arithmetic or algebraic), it permits them to integrate both mathematical end context knowledge to provide an appropriate solution to the event posed. This representation, in the case of research, has been considered the one that allows the proficiency of the interest concepts.

In general terms, it is observed that the representations different types of the invariants play an important role in the contextualized event resolution and the learning activities that have been posed to the students. The approach to learning activities was characterized by because they commuted by different types of representation to until reaching a symbolic representation and obtaining a satisfactory result. In the acting of the students it was detected that when the group addresses the learning activities and builds knowledge, the representation types, found during the research and considered as being proper to the linking of two sciences, are developed gradually at the same pace as the conceptualization of systems of linear algebraic equations in the context of mixing chemical substances. Additionally it enables the student to develop skills to solve new contextualized events that they may be posed.

As it has been mentioned, the students group moves through the representations different types until reaching the symbolic one, which enables the students to construct their own knowledge about the study phenomenon that links mathematical concepts and sciences. That is why, the generation of symbolic representation was discussed in great depth, identifying three related processes, which other types of representation are present. Interpretation and selection process, Structuring process and Operationalization process.



Figurative operating representation (drawing).



Symbolic representation (arithmetic)

Figure 1. Process of selection and interpretation.

Interpretation and selection process, the context is considered as a fundamental part of the event, from the contextualized event the students group performs a selection of information that seems relevant, in it the available prior knowledge is considered and students translate the information into a representation type, such as algebraic (linear equations), arithmetic (simple rule of three), tabular (tables of data) or graphics, even in a figurative operating representation, see Figure 1.

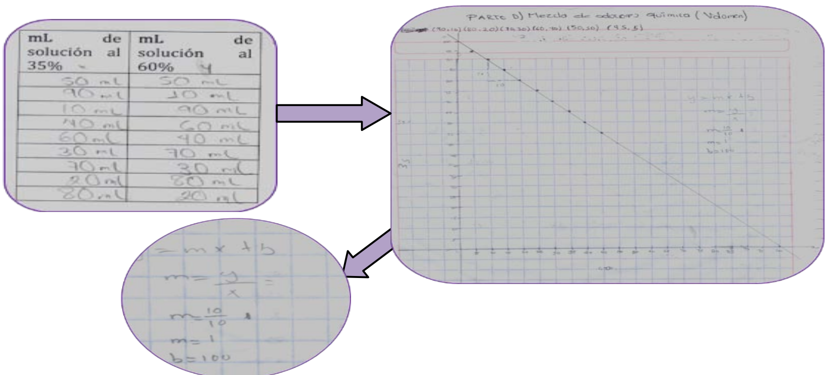


Figure 2. Structuring process.

Structuring process, in this one intervene again the previous knowledge, we resort to analogies with events which have been previously solved and which appear to be similar to the pose done; it seems that the previously solved events are stored in the memory and constitute a part of the knowledge brought into play by the students group, similarly, the procedures and strategies which were followed undergo a restructuration and advance progressively as attempts to solve the event are made. See figure 2.

Operationalization process, it takes place when representations are manipulated and the students group attains the solution of the posed contextualized event. It is identified that during this process the students group applies the operating knowledge that come from their experience and with that the group formulates procedures or strategies. In this process the previous knowledge of the students group plays an important role as they allow modeling the event and working with the mathematical model by symbolic modes of representation that are more operational than the propositional, see figure 3.

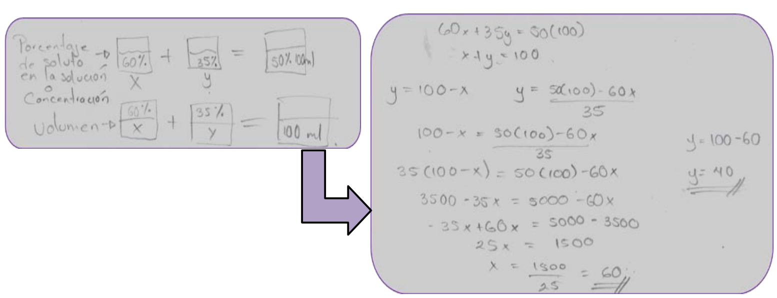

Figure 3. Operationalization process.

Conclusions

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

It can be observed from the research that it has been sought to contribute to the understanding of the knowledge construction of the student in a conceptual content derived from the link between two different contexts, mathematics and technical area of the working field of a Senior Technical in Food Technology. The shown analysis has been addressed paying attention to the action of the student in the solution of contextualized events and teaching activities with systems of linear algebraic equations in the context of matter balance, which constitute a means of analysis upon which the knowledge construction is described. It is a cognitive type study which uses the Conceptual Fields by Vergnaud as a theoretical framework, initially developed to carry out research in elementary education and that has been retaken to explain a contextualized phenomenon at Senior Technical level.

During the analysis of the activities by the students group it was necessary to define the types of representations of the invariants in the schemes, which emerged in a spontaneous way during the students performance. It is truth that the students, at the end of the sessions, have acquired appropriate schemes to face contextualized events that require systems of linear algebraic situations, but, it is necessary to further explore into it, above all in different contexts.

Another important element to be mentioned is that if more diverse contexts are used and more contextualized events are addressed by the student, he could be constructing his knowledge in a more everlasting way and will be able to carry out the transference of mathematical knowledge to other sciences.

SECONDARY MATHEMATICS TEACHERS' CONCEPTIONS OF WORTHWHILE TASKS

Zandra de Araujo

lms1217@uga.edu

With a growing emphasis on task based learning, it is important to examine what constitutes worthwhile mathematics tasks. In this study we examined secondary mathematics teachers' conceptions regarding what constitutes a worthwhile mathematics task. The 27 teachers in this study participated in both focus group and individual interviews. Teachers' conceptions were compared and contrasted with conceptions about worthwhile tasks found in mathematics education literature. Many of the teachers' conceptions aligned with definitions of tasks found in the literature, but we identified additional nuances and pragmatic conceptions. Teachers' conceptions were analyzed and classified. These classifications characterize distinctions among the uses of mathematical tasks that may inform future research.

In his 1994 essay titled *What we Know About Mathematics Curricula*, Schoenfeld explained the benefits of problem solving in mathematics classrooms over the traditional learning of facts and theorems stating, "Large amounts of mathematics can be learned as sensible answers to sensible questions—that is, as part of mathematical sense making, rather than by mastery of bits and pieces of knowledge" (p. 59). This idea of problem or task based learning continues to gain momentum in the United States. National Science Foundation (NSF) funded curricula such as *Connected Mathematics* and the *Interactive Mathematics Program* (IMP) are examples of curricula that build mathematical understanding through the use of mathematical tasks. The National Council of Teachers of Mathematics' (NCTM) recent document *Focus in High School Mathematics: Reasoning and Sense Making* (2009) promotes curricula focused on student reasoning and problem solving, suggesting curricula centered on rich mathematics tasks can help to support this goal. Similarly, the Common Core State Standards' Mathematical Practices' (2010) foci on mathematical problem solving and reasoning seem to suggest that rich mathematical tasks should play a central role in today's mathematics classrooms.

Researchers classify tasks in a variety of ways. Tasks may be sorted by cognitive demand, purpose, or even whether or not they can be considered worthwhile. Though a review of the literature related to tasks revealed a great number of studies examining tasks, teachers' perspectives on tasks were lacking. In this study we sought to examine teachers' conceptions of tasks, more specifically, we sought to understand what teachers consider a worthwhile task.

Prior to a discussion of worthwhile tasks, we must first define the word task as used in this study. We have chosen to use Stein and Smith's (1998) definition of a task, "A segment of classroom activity that is devoted to the development of a particular mathematical idea" (p. 276). With this definition a task may be a single problem or could be a week long project. The following section discusses ways researchers have chosen to classify such tasks and the idea of what precisely constitutes a worthwhile task.

Tasks in the Literature

The literature is rife with discussions of mathematical tasks (e.g. Hiebert et al., 1997; Henningsen & Stein, 1997; NCTM, 2007; Stein & Smith, 1998; Swan, 2008). These studies focus on a variety of aspects of tasks such as enacting tasks (e.g., Stein, Smith, Henningsen, & Silver, 2009) and using tasks for assessment. There have also been several efforts to classify tasks by various criteria. We discuss several of these classifications in the following paragraphs.

Swan (2008) classified tasks according to the processes that they help the learner develop mathematical understandings. The five classifications of task types correspond to the processes of classifying mathematical objects, interpreting multiple representations, evaluating mathematical statements, creating problems, and analyzing reasoning and solutions. This focus on the task outcomes departs from the approach of classifying tasks by the cognitive demands of the task, an approach taken by several researchers.

Stein and Smith (1998) classified tasks by cognitive demand. The classification system consists of four categories of tasks, two related to high cognitive demand and two related to low cognitive demand. Stein and Smith did not perceive of these categories as hierarchical in nature. The use of a variety of tasks from different levels of cognitive demand is supported by the following claim,

> (The authors do not) suggest that all tasks used by a teacher should engage students in cognitively demanding activity, since there may be some occasions on which a teacher might have other goals for a particular lesson, goals that would be better served by a different kind of task. (Stein, et al., 2009, p.5)

This view allows for the flexibility of choosing tasks of varying cognitive demand depending on the desired learning goals; however, recent research has found that students in classrooms that enacted high cognitive demand tasks performed better on assessments that measured problem-solving and mathematical reasoning (AERA, 2006).

In addition to classifying tasks by the aforementioned attributes, there have been efforts to classify tasks by their worth. Hiebert et al. (1997) discussed appropriate tasks. The authors characterized appropriate tasks as those able to be understood by students but also problematize mathematics for the students, and engage students in thinking about important mathematical concepts. These three aspects are also evident in NCTM’s notion of worthwhile tasks.

NCTM’s *Principles for Teaching Mathematics* (1991) discussed yet another classification of tasks, those considered worthwhile. We have used this concept of worthwhile tasks as our conceptual framework for examining teachers’ conceptions. NCTM characterized worthwhile tasks as those that facilitate student interest and intellect, develop students’ mathematical skills, create connections among mathematical ideas, promote problem solving and communication, and take into account students’ backgrounds and dispositions. More recently, NCTM (2007) summarized these attributes stating, “Worthwhile mathematical tasks are those that do not separate mathematical thinking from mathematical concepts or skills, that capture students’ curiosity, and that invite students to speculate and to pursue their hunches” (p.33). While NCTM advocated the use of such tasks, they also acknowledge that teaching with such tasks requires a great deal of planning and knowledge.

Each of these descriptions of tasks in the literature help to build an understanding of tasks and their various uses in the classroom; however, teachers’ voices regarding tasks are noticeably absent from the literature. This study’s purpose is to illustrate the similarities and differences in teachers’ conceptions of mathematical tasks. We also sought to extend the comparison of the teachers’ conceptions with perspectives from the literature on mathematical tasks.

Methods

This study is part of a larger study in which we examined teachers' conceptions of an integrated mathematics curriculum. The participants were 27 secondary mathematics teachers in the first year of state standards implementation. The teachers were identified through referrals from colleagues and recruitment at local professional development workshops. The new standards departed from the traditional secondary mathematics course sequence (algebra, geometry, algebra 2, etc.). The new courses contained algebra, geometry, and data analysis units within a single course. This organization of the content led some people to refer to the courses as integrated. The new standards also led to changes in teaching practice. The state developed mathematical frameworks to reflect its goal of reform oriented teaching practice. These frameworks contain collections of mathematical tasks grouped by curricular units. These tasks were meant to bring together mathematical processes, especially mathematical connections. This new focus was a dramatic change from the prior, more traditional state standards.

The research team conducted 6 focus groups consisting of 4-6 participants for a total of 27 teachers from 9 school districts in northeast Georgia. The purpose of the focus groups was to examine participants' experiences with the implementation of the new state standards. After partially transcribing the focus group data and coding for emerging themes, we purposefully selected 9 participants for in-depth interviews in order to obtain maximum variation (Patton, 2002). These interviews allowed us to gather more information about topics that arose in the focus groups. The interviews were fully transcribed and analyzed using the constant comparative method decoupled from grounded theory (Glaser & Strauss, 1967). A minimum of two researchers participated in each of the rounds of coding to provide internal validity.

Results

To motivate results regarding teachers' conceptions of worthwhile mathematical tasks, it becomes necessary to first consider how our participants described and defined mathematical tasks. During focus groups and in-depth interviews, members of our research team asked participants to draw from their experiences teaching the new standards and to describe a mathematics lesson they considered to be particularly successful with their students. These discussions typically included examples of mathematical tasks that teachers found to be worthwhile for their students. When the idea of task was introduced in the interview setting, often times, the researcher probed for the participant's meaning. Interestingly, one teacher seemed to define a mathematical task by detailing what a task was not:

> If there was only one way to solve a problem, nothing open-ended about it, like word problems in Algebra I. They're not Tasks …There's nothing to engage in, there's nothing to investigate. It doesn't generate any good conversation, and there aren't multiple paths to the same solution.

The negation of this teacher's description seems to imply her definition of a mathematical task. More commonly, teachers described tasks as mathematical problems with multiple paths to a particular solution, allowing students to engage in mathematical processes.

Drawing from participants' definitions, the authors analyzed specific portions of the transcripts when teachers' discussions related to mathematical tasks. We inductively coded the transcripts and developed emergent themes within participants' discussions of worthwhile tasks. In our final stage of analysis, we organized the themes into three broad categories: themes related to the mathematical content, mathematical processes, and practical considerations.

Themes Related to Content

This first category of emergent themes is related to the mathematical content developed within the tasks. Often, teachers talked about the importance of embedding the mathematics within a context, and teachers appreciated tasks that promoted students' construction of mathematics. Both of these themes refer to the ways in which the content should be incorporated into a worthwhile task as well as how the content is presented to students.

Embeds the Mathematics in a Context

During the in-depth interviews, teachers often provided concrete examples of tasks where the mathematical content was situated within an interesting context. For example, several teachers favorably referenced a mathematical task that develops the various points of concurrency. In this task, the mathematics develops within the context of finding an appropriate location for a cell phone tower. Students are asked to determine where to place the cell phone tower in order to provide maximum coverage for three cities (Georgia Department of Education, 2008).

Teachers explained that incorporating a meaningful context was a particularly important characteristic of a worthwhile mathematical task for several reasons. These types of tasks provided their students with opportunities to connect their mathematical knowledge to what teachers called the "real world" and "real world thinking". The context surrounding the mathematics motivated students to engage in and learn essential mathematical content in the task. As one of our teachers explained, "A good task has … good mathematics in it. And…it's a context that kids would be interested in." Many teachers discussed the context as a tool to allow the mathematics to become more relevant for students. The context not only provided motivation for students but also encouraged a deep exploration and construction of mathematical ideas.

Promotes Students' Construction of Mathematics

Within teachers' descriptions of worthwhile tasks were commendations for mathematical tasks that allowed students to construct their own mathematical understandings. Some of the tasks within Georgia's new mathematics framework allowed students to think independently about the mathematics, to struggle with the mathematics, and to construct their own mathematics. For example, one teacher explained, "I think the advantage is that [the task] certainly gives the kids an opportunity to discover things for themselves and lets them be more independent and be more independent learners." A majority of the teachers in this study shared this notion of allowing students to discover mathematics through the tasks and make mathematics their own.

The teachers contrasted worthwhile tasks with tasks that were inundated with leading questions. In general, teachers frowned upon leading questions, stating that the questions did not permit students to freely explore the mathematical ideas posed by the task. Teachers instead favored asking appropriate questions to help students "figure out what is going on." One teacher stated, "They're (students) discovering that you're not telling them… They're actually figuring out what the theorem says without you just coming out and telling them the information." These quotations emphasize the teachers' expectations that worthwhile mathematical tasks should encourage students to explore and investigate the mathematical ideas presented by the task.

Themes Related to Mathematical Processes

The second category of themes relates to the mathematical processes involved as students engage with the mathematical tasks. These processes align to several of NCTM's (2000) Process Standards, namely problem solving, communication, and connections.

Fosters Problem Solving

Worthwhile mathematical tasks provide students with opportunities to engage in problem solving (NCTM, 2000). Therefore, it is not surprising that teachers commonly described worthwhile mathematical tasks as "multi-layered problems" through which students can engage in "real world thinking." These kinds of tasks allow students to use a variety of approaches in order to solve the problem. One teacher said, "I like problems [tasks] in which you can, I guess, when you really have to slow down and think about all different angles." Teachers explained how worthwhile tasks require students to think deeply about the mathematics, because "the biggest difference within those tasks is that all of the sudden they [students] are expected to think on their own and process." One teacher described worthwhile tasks as prompting metacognitive strategies, "I think the task gets them to think about thinking more and to kind of rack their brain… how would I figure that out?" Many times, teachers' conceptions of worthwhile mathematical tasks were located within the intersection of tasks that foster problem solving and tasks that allow students to communicate mathematically, because they claimed mathematical communication aided students in problem solving.

Encourages Mathematical Communication

The participating teachers believed that worthwhile mathematical tasks should be a vehicle to engage students in mathematical communication. In describing the characteristics of tasks that enable such communication, one teacher said, "The task part of the class can focus on the open-ended questions and the open-ended discussion type of thinking that needs to go along with that." Because teachers often considered worthwhile tasks to include multiple paths to the same solution, they expected students to discuss the various approaches used to develop the mathematical concepts within the task. Students were encouraged or expected to work on tasks in groups to develop this mathematical discourse and a depth of understanding. One teacher reported asking students, "Can you tell each other how you did it?" stating that this strategy fostered communication across students. She also commented that worthwhile tasks "just seemed to provide a lot of that conversation." When describing the difference between the new standards and their old method of teaching, the richness of classroom communication was a frequently and positively discussed byproduct of the new standards. Teachers appreciated how students' communication detailing the multiple solution paths within a worthwhile task also generated rich mathematical connections across these conversations.

Provides Opportunities to Make Connections

Teachers' discussions of worthwhile mathematical tasks included the importance of affording students multiple opportunities to make rich mathematical connections. Teachers often equated mathematical learning to making connections. One teacher stated, "I mean to me that is mathematical learning, when I can look at four groups presenting four different paths to the same solution and I can see how your geometric representation is the same thing as what I did algebraically." Making comparisons across the representations help students to develop and recognize mathematical relationships. These connections, facilitated by the tasks, enhanced their students' conceptual understanding.

> If they [students] did it algebraic(ally), geometric(ally), and then another way to look at it. Being able to have that task and summarizing it at the end. You know now, okay, here's little picture, little picture, now let's look at a big picture.

The connections made by students when working through a worthwhile task help students develop a unified picture of mathematics.

Themes Related to Practical Considerations

Teachers frequently focused their discussion on more practical considerations of worthwhile tasks. These practical considerations perhaps arose from the dramatic change in practice that was demanded from implementing task based curriculum. Although the impetus for the discussion of these issues may be a byproduct of the teachers being in the midst of this implementation, these practical considerations were addressed by each of the teachers.

Achievable

Teachers explained worthwhile tasks should be accessible to all students, and tasks need to be achievable in a variety of ways. First, a worthwhile task must take into account students' mathematical backgrounds, allowing them to progress through the task successfully. More importantly, teachers shared the need for students to recognize that they had the ability to work though the task with success. One teacher said, "A good task would be achievable, meaning that the students really think that they can do it." Second, many of the tasks provided by the new mathematics framework were rather lengthy. So long, in fact, these tasks seemed impossible to complete, leading teachers to proclaim that the length of the tasks needed to be achievable as well. Echoing this concern, a teacher shared, "Achievable. They can't be 25 pages long and when the kid looks at it, say, 'Oh, this is impossible.'" Finally, all of our participating teachers expressed a desire for all of their students to experience success in this new task based environment. In order to achieve success, several teachers emphasized that worthwhile tasks need to allow for differentiation among students. One teacher remarked, "A good task has to be accessible to all students at some level. I believe that strongly. What do they call it… like multiple entry and exit points for a task, everybody should be able to do something."

Standards Based

The teachers wanted their students to be successful on the end of course exams administered by the state; thus, teachers characterized worthwhile mathematical tasks as tasks that focused on the content standards students were required to master. One teacher stated, "Good ones (tasks) are focused on the standards that we are trying to teach." Another teacher addressed her concern for the state standards stating,

> I have certain standards that I'm supposed to teach, and then the tasks need to reflect those standards. You can't just pick it [tasks] because it's a fun problem to engage it. I mean by law I have to teach certain standards, you know, so I do have to choose task that will…that I can use to pull out specific mathematical ideas.

The majority of teachers echoed this concern, and this concern influenced their selection of tasks. The notion of standards based, achievable tasks encompassed the practical considerations important to our teachers' conceptions of worthwhile tasks.

Discussion

After conducting our analysis, we returned to the literature on worthwhile tasks. Typically, there exists a gap between literature in mathematics education and practice. As researchers, we wondered to what extent were teachers' conceptions of worthwhile mathematical tasks reflected in the literature. The juxtaposition of the participating teachers' conceptions with classifications provided by the literature in mathematics education regarding worthwhile mathematical tasks proved to be rather illuminating, providing implications for research and practice.

We used NCTM's (1991) classification of defining characteristics of worthwhile tasks to make our comparison. We created a Venn diagram and labeled one set as Classifications from Literature and the other as Conceptions from Practice (see Figure 1). As seen in the intersection of the two sets, many of the classifications and conceptions overlap. We believe several similarities exist between research and practice as well as some interesting differences for further discussion and analysis. For example, when reviewing the similarities across sets, we noticed that NCTM suggests worthwhile tasks facilitate student interest whereas our participating teachers appreciated embedding a task within a context to make the mathematics relevant to students. As is evident in Figure 1, several additional similarities exist; yet, two important differences emerge through this comparison. First, one of NCTM's classifications identified worthwhile tasks as tasks that develop students' mathematical skills. However, our participating teachers saw the development of skills as a completely separate activity from tasks in the classroom. Second, several participating teachers emphasized the necessity for tasks to focus on the content standards they are expected to teach from the state's curriculum frameworks in order for the task to be worthwhile, whereas this characteristic is not located within NCTM's classifications. This difference seems to capture the important and practical realities of teaching. As mathematics educators, we must consider possible implications these findings have for both preservice teacher education as well as professional development.

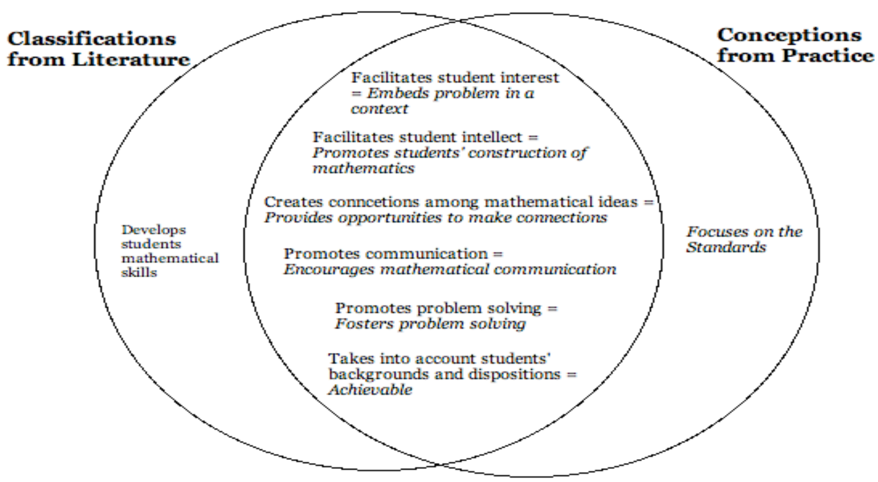

Figure 1: Worthwhile tasks as classified in research and conceived of by teachers

In the Teaching Principle, NCTM (2000) concludes their discussion of worthwhile tasks by stating, "Worthwhile tasks alone are not sufficient for effective teaching" (p. 19). Similarly, our research findings do not provide a conclusion regarding worthwhile tasks, but, rather, a beginning. Many of our participants discussed the difficulty of either finding or developing these worthwhile mathematical tasks. One participant shared,

> An appropriate task or word problem, which to the maximum extent included multiple disciplines and gave as many chances as possible to make the learning relevant … Those are really hard to write. If you find one, you hang on to it, forever.

It is important for both professional development and teacher education programs to support teachers in developing such worthwhile tasks. This study provides an important initial step toward the inclusion of teachers in discussions of worthwhile tasks. Further research is needed to understand how teachers develop and modify tasks to make them worthwhile. As research in mathematics education continues to study worthwhile mathematics tasks, research is needed to inform practice. This statement assumes that research is relevant to practice. Therefore, as researchers, in order for us to make research more relevant to practice, we believe carefully listening to teachers describe their practice is an excellent place to start.

TEXTBOOK IMPLEMENTATION IN RURAL SECONDARY INTEGRATED MATHEMATICS CLASSROOMS

Erin E. Krupa
Montclair State University
krupae@mail.montclair.edu

Although professional development can help teachers become familiar with new curricular materials, implementing the materials can be difficult for teachers. This paper presents results from a study of teachers' implementation of an integrated mathematics curriculum in rural secondary schools following their participation in a professional development. Results show teachers are primarily using the textbook for their instruction, but that they implement less of the textbook content in higher level mathematics and struggle to find a balance implementing the content across content strands. These results have important implications for researchers conducting curricular evaluations and for the creation of effective professional development.

Introduction

It is important that claims made about curricular effectiveness include measures to judge the adequacy of implementation (National Research Council (NRC), 2004; Senk & Thompson, 2003). The NRC further noted the importance of documenting the faithfulness of implementation and recommended researchers document the extent of coverage or "implementation fidelity" of the curricular materials. Implementation fidelity measures the extent to which textbook materials are used for instruction and are not indicative of the quality of teaching (McNaught, Tarr, & Grouws, 2008; NRC, 2004).

Reform efforts in mathematics have lead to the creation of curricular materials that focus on strengthening the mathematical knowledge of all students and are guided by instructional practices that promoted problem solving, communication, reasoning, and creating mathematical connections (Senk & Thompson, 2003). However, implementing reform mathematics curricula represents a challenging transition for many teachers (Ziebarth, 2003). Teachers' beliefs and backgrounds greatly influence how they implement curricula, potentially causing the implemented curricula to be significantly different from the developers' intended curricula (Ball & Cohen, 1996; Remillard, 2000) and from a teacher's own intentions (Stein, Remillard, & Smith, 2007; Stein & Smith, 2010). Therefore, it cannot be assumed that access to teachers' guides and curriculum materials will ensure proper implementation (Scott, 1994), nor that teachers within the same school will implement curricula materials in the same way (Bowzer, 2008; Chávez, 2003; Stein, et al., 2007).

The purpose of this paper is to report findings on teachers' implementation of a reform mathematics textbook in rural high schools following their participation in a professional development. This research is an important step towards determining the extent to which the textbook impacted student achievement and the extent to which the textbook is used for instruction.

Theoretical Perspective

The Comparing Options in Secondary Mathematics: Investigating Curriculum (COSMIC) research team was designed to evaluate high school students' mathematics learning from different curricular programs (COSMIC, 2005). They have provided methodological approaches

Wiest, L. R., & Lamberg, T. (Eds.). (2011). Proceedings of the 33rd Annual Meeting of the North American Chapter of the International Group for the Psychology of Mathematics Education. Reno, NV: University of Nevada, Reno.

and instruments to document and measure implementation fidelity. The COSMIC team has made great strides in the field of curricular evaluation and, in particular, in creating innovative ways to measure implementation fidelity. They have created indices for *opportunity to learn* (OTL), *extent of textbook implementation* (ETI), and *textbook content taught* (TCT).

OTL, ETI, TCT Implementation Indices

The COSMIC team measured the OTL, ETI, and TCT through Table of Contents Records (TOC-logs), which were self reported by the teachers and customized for the textbook they were using (McNaught, et al., 2008). For each lesson of the textbook, teachers indicated if they taught the content (a) primarily from the textbook, (b) primarily from the textbook with some supplementation, (c) primarily from an alternative source, or (d) not at all (McNaught, et al., 2008). The OTL index measured the percentage of textbook content that was taught, either solely from the textbook or through supplemental materials. The ETI index weighted the options in the TOC-logs, giving the content taught primarily from the textbook the most weight (a weight of one), content with some supplementation a weight of two-thirds, content mostly from alternative sources a weight one-third, and content not taught a weight of zero. The weights were then summed and divided by the total number of lessons contained in the textbook (for additional information: McNaught, Tarr, & Sears, 2010; McNaught, et al., 2008). This measured the degree to which the textbook was used directly to teach the content. Similarly, the TCT index used the same weighted sum but divided by the total number of lessons taught through any means. This is a measure of how the textbook was used to teach content in the textbook and ignores the topics students were not taught. Each of these three indices was measured at the course level.

McNaught et al. (2010) analyzed data from 174 TOC-logs collected from teachers using both an integrated and subject specific curriculum. Across the teachers using integrated materials, they found the mean OTL index was 60.81 with a standard deviation of 19.91, the mean ETI was 50.73, with a standard deviation of 20.20, and the mean TCT was 81.96 with standard deviation 14.50. While teachers using an integrated curriculum are covering just over 60% of the textbook content, they rarely use alternative sources for their instruction.

Context

The North Carolina Integrated Mathematics Project

The North Carolina Integrated Mathematics Project (NCIM) was developed to create and support a community of teachers using the *Core-Plus Mathematics* (CPMP) (Coxford, et al., 2001) integrated curriculum materials, particularly in high needs schools. Spread throughout rural parts of the state, the seven partner schools in the NCIM project were identified as low-performing based on North Carolina accountability measures. At the time of this study, the average student population for the project schools ranged between 110 to 163 students and the ethnic make-up consisted of: 1% American Indian or Asian, 6% Hispanic, 16% White, and 77% Black. Approximately 72.8% of students at each school qualified for free and reduced lunch.

To prepare teachers to implement CPMP, in order to strengthen STEM education at these schools, the project directors and evaluation team designed four components for the NCIM professional development. The four main elements of the professional development model were (1) a summer workshop providing in-depth education on use of curricular materials (one or two weeks), (2) a web-based environment supporting information exchange, (3) two face-to-face follow-up conferences, and (4) instructional coaches who visited each site monthly.

Methods

Participants

The NCIM project has grown since its inception in the spring of 2008 to include new teachers and has lost two due to teacher turnover. At the time of this study, 12 teachers in the NCIM professional development received instructional coach visits each month and took part in the other components of the project. Each of these 12 teachers began teaching CPMP for the first time based on their schools' participation in the NCIM project.

Data Collection

To measure the implementation fidelity of teachers using the CPMP materials, NCIM project teachers completed TOC-logs (McNaught, et al., 2008) for each course they taught. These logs were replicas of the table of contents in the CPMP textbooks so that teachers readily recalled the material they taught. These were provided to teachers at the beginning of the semester, and teachers returned portions of the logs throughout the school year.

Analysis

This analysis was based on the 15 TOC-logs that were completed during the 2008-2009 and 2009-2010 school years. OTL, TCT, and ETI indices were computed using the COSMIC approach (McNaught, et al., 2008). It is important to note that teachers completed one TOC-log for each unique course they taught. For example if they taught two sections of Course 2 and one section of Course 3, then they would have one measure of OTL, TCT, and ETI for Course 2, with both sections having the same measures, and one measure of each for Course 3.

Due to the sample size, to determine quantitative differences in teachers' implementation across courses and content strands in the textbook, the Kruskal-Wallis distribution free test (Hollander & Wolf, 1999) was used. The Jonckeere post-hoc test (Hollander & Wolfe, 1999) was used to test for ordered alternatives to see if there was a decrease in the indices across the course sequence or content strands. Finally, Dunn's Test (Elliott & Hynan, 2010), a nonparametric multiple comparisons test based on pair-wise rankings, was used to determine differences among specific groups.

Results

Opportunity to Learn

The mean OTL index for NCIM teachers was 52.18 with a standard deviation of 16.15 (Figure 1). These data indicate on average just over half of the content in the CPMP textbooks was covered, though there was considerable variation among teachers' OTL indices.

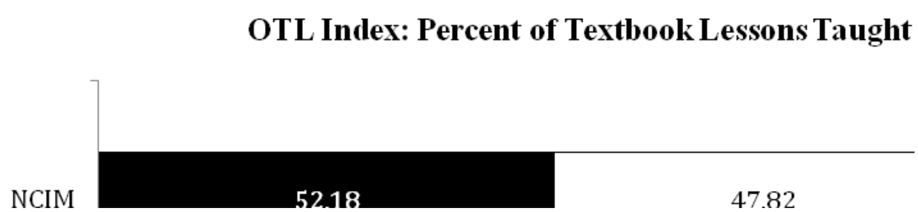

Figure 1. Summary of mean OTL indices for NCIM project teachers.
Note. The heavy shading indicates content taught primarily from textbook, with some supplements, or primarily from an alternative source. White space indicates content not taught.

Extent of Textbook Implementation

Recall the ETI index is a weighted measure describing the degree that the textbook, rather than other materials, was used to teach the content. The NCIM teachers had a mean ETI index of 49.30, with standard deviation 16.41. It is also helpful to look at the ETI index disaggregated by the weighted options: content taught primarily from the textbook, with some supplementation, primarily from alternative sources, or not at all (Figure 2). From reviewing the figure, it appears the NCIM project teachers rarely supplement the textbook material.

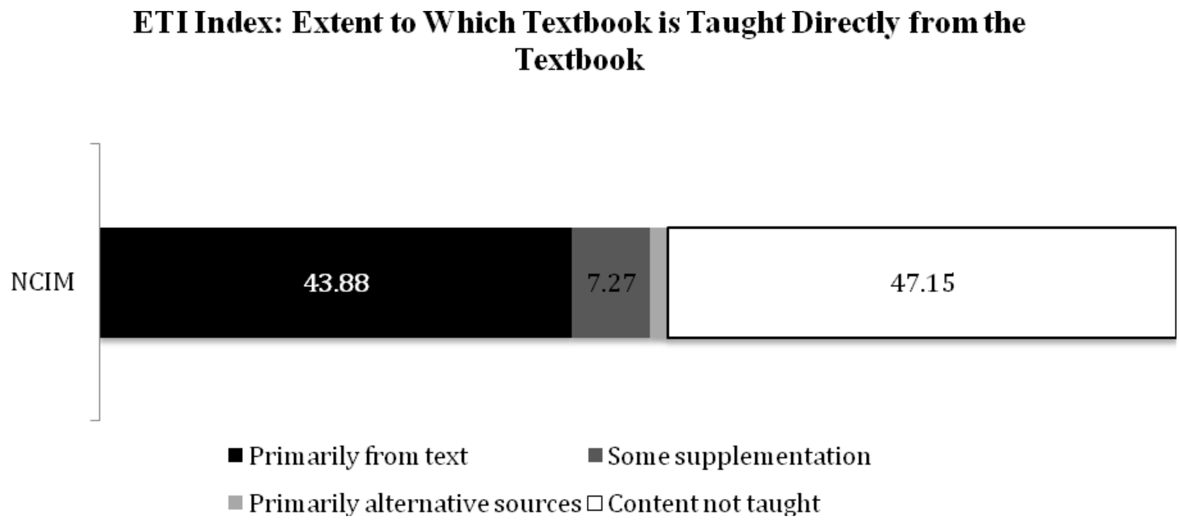

Figure 2. Summary of ETI indices for NCIM project teachers.

Textbook Content Taught

Recall that the TCT index restricts the focus to only the CPMP content that was taught. The mean TCT index for NCIM teachers was 91.64 with standard deviation 7.52. The differences in the TCT indices became more prevalent when considering the TCT indices for content taught primarily from the textbook, with supplementation, and from alternative sources (Figure 3). This suggests that NCIM teachers primarily used the textbook for their instruction and very rarely used alternative sources.

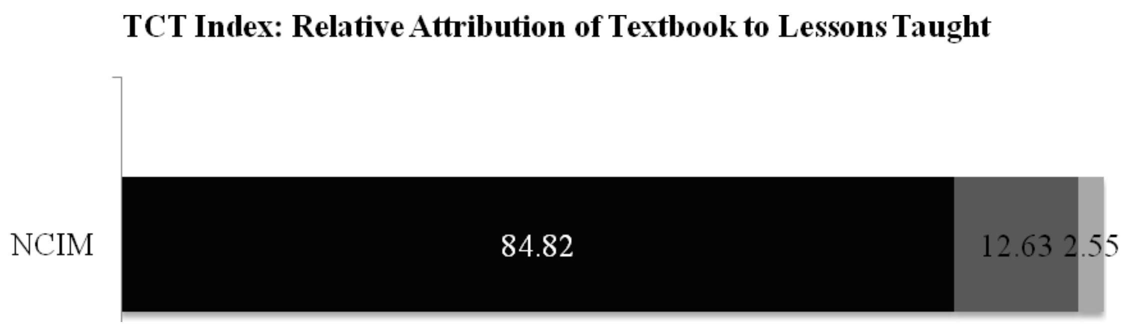

Figure 3. Summary of TCT index for NCIM project teachers

Across Courses

The schools involved in the NCIM project began as ninth grade academies and added an additional grade level each year until they had their first senior class. There was only one mathematics teacher at each school until the second or third year the school was open. As a result it is interesting to track teachers implementation of the curriculum as they progress through the course sequence as instructors. The mean for each implementation index across the first three integrated courses is given in Table 1. There was a significant decrease for the OTL $(p = 0.008)$ and ETI $(p = 0.03)$ indices with each subsequent course that was taught. Thus, as students continued through the integrated sequence, they had less opportunity to learn the material in the text. The TCT is still high, above 85% for each course. From this we can conclude that when NCIM teachers taught content in the textbook, they were primarily using the textbook and not supplemental materials. These findings also suggest that teachers of Courses 2 and 3 need continuous support throughout their implementation of CPMP.

Table 1. Average Implementation Fidelity Ratings Across Courses Taught by NCIM Teachers

	OTL	ETI	TCT
Course 1	63.21	60.12	94.92
Course 2	55.03	52.68	87.89
Course 3	43.38	39.22	91.89

Similar findings can be seen in the implementation indices of individual teachers, Nicole, Maria, and Felicity, as they transitioned to teaching higher sequenced courses (Table 2). It is interesting to point out that Nicole's OTL and ETI indices dropped more than 20 points each from Spring 2009 to Fall 2009 though she was teaching the same course. She completed the Course 2 workshop during the summer of 2008 and the Course 3 workshop during the summer of 2009. Perhaps her indices were higher the semester following her participation in the Course 2 workshop. Another plausible explanation is that the first Course 2 class was a yearlong course (two semesters), while the course she taught in the fall of 2009 was a 90-minute block course (one semester). Having the material spread throughout an entire school year provided her with more time to get through the material.

Table 2. Individual NCIM Teacher's Implementation Ratings Over Time

Teacher	**Year**	**Course**	**OTL**	**ETI**	**TCT**
Nicole	Fall 08	Course 1	74.29	68.57	92.31
Nicole	2008-2009*	Course 2	66.15	64.10	96.90
Nicole	Fall 09	Course 2	44.62	41.03	91.95
Maria	Fall 08	Course 2	65.00	75.38	75.38
Maria	Fall 09	Course 3	36.76	33.82	92.00

Maria	Spring 2010	Course 4	26.09	26.09	100.00
Felicity	Fall 09	Course 1	48.57	43.33	89.22
Felicity	Spring 2010	Course 2	38.46	31.79	82.67

* This was a yearlong course.

It is evident from these results that NCIM teachers struggled to teach the content in the textbook as they progress through the sequence of courses.

Content Strands

In her dissertation, McNaught (2009) identified which units in CPMP corresponded to four different content strands, to determine the differences in implementation across major topics. The four strands were: Algebra and Function, Probability and Statistics, Geometry and Trigonometry, and Discrete Mathematics. Recall the fourth component of our professional development model included visits from an instructional coach. Instructional coaches completed reports following each classroom visits, and these reports highlighted that our project teachers were skipping units of the textbook. To determine if there were differences in the topics taught by NCIM teachers, an approach similar to McNaught's was utilized. Using the table of contents in the second edition of the textbook, each unit of each course was aligned to one (sometimes two) of the content strands. The OTL, ETI, and TCT indices were recalculated for each teacher for each of the four content strands (Table 3).

Table 3. Average Implementation Indices Across Content Strands

Content Strand	OTL	ETI	TCT
Algebra	84.17	76.83	91.20
Statistics	38.98	37.84	82.49
Geometry	37.50	36.94	77.43
Discrete Math	16.37	15.77	26.19

The nonparametric Kruskal-Wallis distribution free test (Hollander & Wolf, 1999) was used to determine if there were differences in the implementation indices across the four content strands. There were significant differences in textbook use across teachers and content strands for each of the indices, OTL $(p < .0001)$, ETI $(p < .0001)$, and TCT $(p < .01)$.

The Jonckeere post-hoc test (Hollander & Wolfe, 1999) was used to test for ordered alternatives to see if there was a decrease in the indices across the ordered strands: Algebra and Function, Probability and Statistics, Geometry and Trigonometry, and Discrete Mathematics. Results show evidence that all three indices decrease along the four content strands, OTL $(p < 0.05)$, ETI $(p < 0.0001)$, and TCT $(p < 0.05)$. This would imply that the average OTL for the Algebra and Function content strand is greater than the other three, yet the OTL for the Probability and Statistics strand is greater than the Geometry and Discrete Mathematics OTL.

Dunn's Test, a nonparametric multiple comparisons test based on pair-wise rankings, was used to determine which content strands differ in location, when $\alpha = 0.05$. The OTL for Algebra $(\bar{x} = 84.17)$ was significantly different than each of the other content strands; Statistics $(\bar{x} = 39.98)$, Geometry $(\bar{x} = 37.50)$, and Discrete $(\bar{x} = 16.38)$.

Using the ETI index, there were significant differences between the Algebra $(\bar{x} = 44.18)$ strand and all other strands; Statistics $(\bar{x} = 27.21)$, Geometry $(\bar{x} = 26.86)$, and Discrete $(\bar{x} = 15.75)$. These results were favorable to Algebra, suggesting students were exposed to more Algebra content than the other strands. The results from the TCT index showed differences between Discrete Math $(\bar{x} = 16.5)$ and both Statistics $(\bar{x} = 34.79)$ and Geometry $(\bar{x} = 33.54)$. The TCT for Algebra $(\bar{x} = 29.19)$ was not significantly different than any other content strand. These findings suggest students had more of an opportunity to learn Algebra than the other content areas. The Algebra topics are currently covered on state assessments and seem to be the main focus of teachers' instruction. It is evident from workshop evaluations that many of the statistics and discrete math topics are unfamiliar to these teachers.

Taken together these findings point to the wide variance in implementation across the four main content strands in the textbook. This also provides empirical evidence to suggest teachers were skipping major units in the textbook. These data need to be further triangulated with interviews from the teachers and the instructional coach reports to determine *why* or *how* they chose to skip sections of the textbook.

Discussion/Conclusions

Teachers in the NCIM project used the content from the textbook and primarily taught the content from the textbook, however this does not imply their instruction was consistent with the written text. Next steps in this research will be to conduct classroom observations to understand *how* the content is being taught, to conduct interviews to determine how teachers make decisions about what content to teach, and using these indices in measures of student achievement. Only after fully understanding how teachers implement curriculum can we begin to measure the impact on student achievement. The research conducted in the paper provides evidence that just over half of the content in the textbook is being taught, with the major focus on the Algebra units. There is also indication that teachers need on-going support in their first three years of implementation and as they move to teaching higher courses in the CPMP sequence.

ANALYSIS OF THE MOTIVATION AND ACHIEVEMENT OF SECONDARY STUDENTS ENROLLED IN A SUMMER MATHEMATICS ACADEMY

April Kubishta
Arizona State University

James A. Middleton
Arizona State University
jimbo@asu.edu

Achievement and motivational data was collected from 465 students enrolled in a Summer Mathematics Academy designed to provide enrichment and accelerated courses for secondary students. Academy courses were designed taking into account motivational variables associated with the development of intrinsic motivation, a mastery goal orientation, and personal choice and challenging tasks. Results show that Academy participants scored at an extremely high level on the Terranova and PSAT assessments. Motivation was assessed using Personal Constructs Theory. Results are consistent with earlier work that emphasizes Interest and Challenge/Control tradeoffs in determining intrinsic motivation in students.

Summer Mathematics Programs and Student Motivation

This paper examines the academic achievement and motivation of secondary-age students enrolled in a summer credit advancement program in mathematics. In contrast to compulsory academic-year coursework, there is practically no research conducted about specialized summer programs in mathematics. In particular, these programs' effects on academic achievement and motivation have not been extensively studied even though many schools are now implementing summer programs to in hopes of boosting academic success. This paper will focus on credit-advancement programs and not necessarily remedial or enrichment-only programs. Being that there has been little research done on these credit advancement programs, other academic programs that have been researched have been used to help make some of the theoretical and empirical arguments in this paper.

Many studies have found that summer vacation influences a direct decline in academic achievement (Cooper & Nye et. al., 1996, Entwistle & Alexander, 1992). In fact, summer vacation accounts for about a month's loss of academic learning or about a tenth of a standard deviation on students' academic achievement (Cooper & Nye et. al., 1996). Not surprisingly, the effects of summer are more damaging on mathematics scores than other subject areas tested. Moreover, the summer months may have a particularly negative effect on gifted students who become bored and then underachieve the subsequent school year (Li et. al, 2009).

A small but growing number of studies show that bridging students' academic year experiences through appropriate acceleration and/or enrichment programs in the summer can increase students' mathematical understanding and their skills (Tichenor & Plavchan, 2010). These studies show that an important part of a camp's design should be to provide a learning-enriched atmosphere, allow for risk-taking, and a demonstrated passion for mathematics. With this type of design for the summer camps, the students have shown to appreciate, enjoy, and learn math thereby increasing their own confidence in math.

Some would argue that because of the pacing required of these summer programs, lasting retention would not be evident, and thus no real overall increase in academic achievement would persist. In fact, the impact of summer programs tend to be long lasting (Barnett, 1993), involving increased knowledge and achievement in mathematics subject matter (Knapp, 2007), and in an increase in the probability of taking advanced mathematics courses in the future. (Li et. al, 2009).

Motivation Related Variables

Part of the puzzle when designing summer programs is to build in appropriate motivational appeal. Particularly for acceleration and other non-compulsory programs, students and their parents have choice in enrolling and persisting. The challenge of the program, its utility and the kinds of interests it fosters can be critical for its continued success. So it becomes important to examine the reasons students have for enrolling in off-calendar offerings, and the degree to which the offerings fit their goals and values. Students who are intrinsically motivated, for example, will show resiliency towards the given task even though the activity may be difficult (Gottfried, 1983; Schunk, 1990) without the need of any type of reward to begin or finish the task (Beck, 1978; Deci 1975; Woolfolk, 1990). Additionally, intrinsically motivated students will be more likely to retain the concepts learned and gain confidence about engaging in unfamiliar learning activities (Poonam, 1997). Of course, a student who is assigned a task in which they have little interest value is less likely to exhibit excitement and persistence than a task that strikes curiosity and interest.

Overall, research shows that a higher level of intrinsic motivation should lead to retention of concepts, higher confidence, and thereby, higher academic achievement. Significant and positive correlations have been found between intrinsic motivation and achievement as measured by standardized achievement tests in specific subjects, such as mathematics and reading for early-elementary, late-elementary, and junior high school students (Adelman, 1978; Gottfried, 1985, 1990). It would seem likely then that academic intrinsic motivation would also be positively related to achievement in these specialized summer mathematics programs at the high school level.

The remainder of this manuscript will describe the design of a summer acceleration program for middle- and high-school students in the greater Phoenix Arizona area, and analyze the achievement and motivational profiles of students enrolled in the program.

Method

Summer Math Academy

The Summer Math Academy was offered at a large, urban high school by its mathematics faculty. At the time of the research, the summer program was in its tenth year running with three years of previous achievement data collected. We focus only on these three years from 2007 to 2010. Prior to 2006, the Academy only offered Algebra courses. In 2007 that the Academy began to offer Pre Algebra and a limited number of Geometry courses to advance students through these basic courses in high school. The few Geometry students in 2007 were organized in a more guided, but self-taught environment. These students were in the same room as one of the Algebra classes. In 2008, the Math Academy decided to offer 6th grade and 7th grade mathematics as well as more Geometry courses. Starting in 2008, the Geometry courses were not organized as independent studies but had their own classroom with a geometry-specific teacher.

Many of the students who sign up for the Summer Math Academy report preparing themselves for tough courses and academic goals. A good portion of the students are preparing to take Advanced Placement Calculus and Advanced Placement Statistics which are required for many college majors. By 2010 it became possible through the academy, for students to take AP Calculus I, AP Calculus II, AP Vector Calculus, AP Differential Equations, and in the near future, possibly Linear Algebra. In addition, many students were preparing to exceed the

Arizona Instrument to Measure Standards mathematics tests to qualify for college scholarships, be competitive in the future job market, and complete the state's four year high school mathematics requirement.

For middle schoolers, the curriculum in the algebra and honors geometry courses sufficed to receive high school math credit. Overall, there was a wide variety of students as the youngest enrolled were about to enter into the fourth grade while the oldest were going into the tenth grade.

There are a total of 28 days of instruction in the Summer Math Academy each year. The first day begins four days following the end of the regular school year. In the three years this study focused on, the Academy ran from Monday through Thursday with every Friday off for a total of seven weeks. The mathematics program would start at 7:30 a.m. and finish at 11:30 a.m. each day. The students had a five-minute break every hour.

Participants

In total, there were 465 students that had attended the Academy from the first three years while a total of 444 students were present the summer of 2010. The breakdown of the number of students enrolled in each course by year can be found in Table 1. Note that some students enrolled in the summer Academy for more than one year and thus the table does not reflect unique students. However, the 465 total is the number of unique students that completed the Academy. Just about every year in the camp's history, students were denied enrollment because there were a fixed number of teachers. This was to ensure that no classroom had too many students in it.

	6th Grade Math	7th Grade Math	Pre Algebra	Algebra	Geometry	Total
2007	-	-	62	59	7	128
2008	22	17	35	71	12	157
2009	27	43	45	110	64	289
Total	49	60	142	240	83	465

Table 1. The number of participants by year in each course at the math camp

Design of Camp Experiences

Since intrinsic motivation generally increases student engagement and achievement the Summer Math Academy attempted to provide students choices of topics to choose from (Patall et. al, 2008). We attempted to provide contextualization, personalization, and problem choice to the extent possible in each course (e.g., Cordova & Lepper, 1996). Moreover, students in most classes could choose their own pace when working individually (Patall et. al, 2008).

Students are also more likely to perceive successful outcomes when they are in environments that promote mastery motivation (Gottfried, 1983; Weiner, 1979). We felt that helping students create mastery goals and fulfilling them through applied effort would intrinsically motivate students (Gottfried, 1983; Harter, 1974, 1977). Because intrinsically motivating tasks are challenging, the academy encouraged students to choose advanced mathematics courses, in order to push them to the extent of their abilities. But, there needed to be a safe environment that encouraged students to fail positively. We build this in, for example, by allowing students to attempt the tasks multiple times to approach mastery. The flexibility of the Academy's camp environment also allowed students to monitor themselves, go beyond the presented content and discover deeper connections between concepts,. All of those aspects have been shown to influence motivation positively.

Achievement Measures

The students took a pre-test and a post-test to help determine the effect of the Academy camp on their academic achievement. The Arizona Instrument to Measure Standards Grade 8 test scores were collected as students took this test prior to entering the Math Academy. As a post-test, scores on the Terra Nova and PSAT were collected as most students took these after entering the Academy. Any student who took the PSAT and/or Terra Nova before entering the math academy had their scores excluded from the data.

Measures of Motivation: Repertory Grid Techniques

This study used Repertory Grid techniques to determine the content and structure of students' motivations (e.g., Middleton, 1995). Motivational constructs for the algebra and geometry courses were elicited separately as these were distinct classes that students took—there was no overlap in students taking the courses—and because the content of those courses was hypothesized to motivate students differently.

Construct elicitation

A Motivational Repertory Grid was developed for the Algebra course and Geometry course. For each course, ten different major algebraic or geometric topics emphasized in the course were chosen. Students were presented with 45 (${}_{10}C_2/2$) pairs of these topics in random order. They were asked to report what made one topic more preferable than the other topic. Students reasons for choosing one topic over the other are considered their *personal constructs* related to motivation. Students' personal constructs were tabulated and rank ordered. The top ten identified constructs were placed onto rows on a Repertory Grid, and the 10 topics used to elicit constructs were arranged on the columns of the Grid. Students were then asked to rate, on a scale of 1 to 10, the degree to which each *construct* described each *topic.* The final grid for each student then, was a 10 by 10 grid of ratings with each construct being assessed across each topic—for a total of 100 ratings.

Students' ratings were summed and the mean score in each cell computed. These mean scores were then used to create a Group Repertory Grid, representing an average motivational set for the group of students in each course. Table 2 lists the key topics used to elicit constructs, and the motivational constructs obtained, from algebra and geometry courses respectively.

Geometry Topics	Algebra Topics	Motivation Factors
Perpendicular Bisector and Theorems	Ratios and Proportions	It is more Fun to Learn
Converse/Inverse/Contrapositive	Finding the Equation of a Line	It is more Interesting
Parrallel Lines with Transversal make Angles Congruent or Supplemental	Order of Operations (PEMDAS)	It is Easier to Learn
Addition/Subtraction/Multiplication/ Division Properties	Multiplying Polynomials (FOIL)	It is more Challenging
Writing Two-Column Proofs	Graphing Linear Equations	I can Visualize the Solutions
Perpendicular Line to a Plane	Factoring Polynomials	I get to Decide How to do Problem
Similar Triangles	Finding Slope	I can Apply it to Real Life
Congruent Triangles	Inequalities (> <)	I can Memorize How to do It
Properties of Polygons	Word Problems	It Makes Sense to Me
Angles of Triangles and other Polygons (Exterior angle, Interior Angles)	Solving Systems of Linear Equations (Substitution/Elimination)	It Helps Me Understand more Concepts in Math

Table 2. The course topics and motivation factors found in the Motivation Repertory Grid

Results

Analysis of Achievement Scores

To analyze the effect of mathematics academic achievement, scores from the AIMS, Terranova and PSAT standardized tests were collected and analyzed. SThe Terra Nova is taken in the spring of the ninth grade and the PSAT is typically taken the fall of their junior year.

The rank of the students who attended math camp on the standardized tests are compared. It would seem reasonable that within this small group, the ranking of the students should stay consistent from year to year i.e. the top/low ranked students should stay in the top/low ranking. Then the percentiles on the tests of these students are compared to the remainder of the population to see if there is an overall jump for the math Academy students as a group in the mathematics achievement scores.

Table 3. *Students who went to camp multiple times and their scores on PSAT and TerraNova*

	Number of TN students	Average TN Percentile	Number of PSAT students	Average PSAT Percentile
All Student's Average	179	81.62	97	78.20
Camp Twice	13	81.08	9	79
Camp	166	81.70	88	78.20

Once				

Table 3. Scores of students attending multiple times on PSAT and TerraNova

It is unclear from our analyses, whether or not the Summer Academy greatly enhanced students' achievement. The extremely high average performance across the board on the Terranova, and the PSAT constitute a kind of ceiling effect. Moreover, because only a handful of students had taken the Summer Academy more than once, any group differences are not detectable statistically.

Cluster Analysis of Repertory Grids

Group Repertory Grids were subjected to hierarchical cluster analysis (Wards Method), using a squared-Euclidean distance metric. This analysis arranges the constructs in the grid in a 10-dimensional space, using a linear combination of the topics to determine their relative positions in the space and their relative distances from each other. PSAW (SPSS) version 18 was the software package used for the analysis.

Results are displayed using a dendrogram, which illustrates the degree to which constructs are similar to each other. Constructs most similar (most close in squared Euclidean distance) are arranged most proximal on the dendrogram, and constructs least similar are arranged farther apart (See Figures 1 and 2).

From the dendrogram, three clearly defined clusters of constructs emerged from the analysis. The first and most tightly organized cluster deals with the interest level of the topics. Similar to Middleton (1995) findings with gifted elementary students, our analysis shows that Interest is a major factor in determining students' beliefs about the motivational value of their programs. Also consistent with their work, we found that the tradeoffs between challenge and control are a critical factor. Sense making, not surprisingly, rounded out the three clusters. Because the summer Academy emphasized personal choice and control, sense making, multiple attempts and other motivation-related design choices, we have some confidence that the Algebra program was, by and large, appealing and effective for participants.

Figure 1 shows the structure of students' motivational constructs for the Algebra courses.

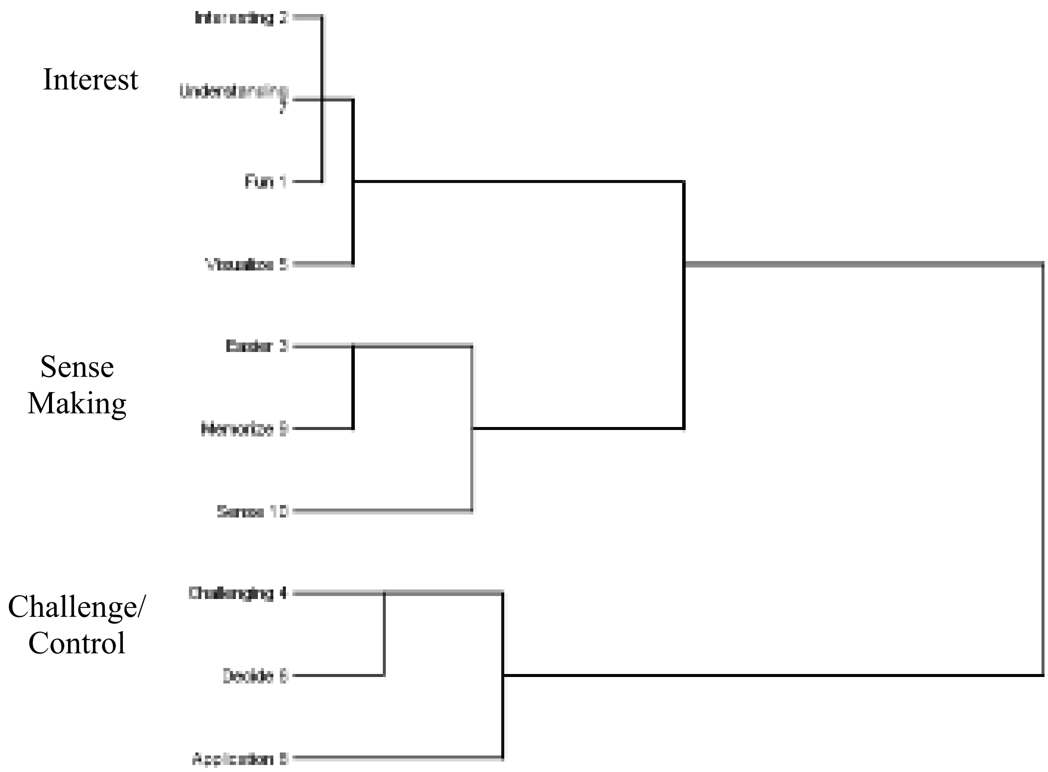

Figure 1. Organization of students' motivational constructs re: Algebra Course

Results for the Geometry course are similar (See Figure 2). Again, there were three defined clusters of constructs, organized around Interests, Sense Making, and Challenge/Control tradeoffs. For Geometry, however, the division between Interest and Sense Making was less pronounced than that for the Algebra Courses.

When the actual content of the courses was analyzed, one interesting result was manifest: For Algebra, Word Problems was rated as an entirely different topic, motivationally, than any of the others in the course. Solving word problems, in essence is seen as something separate from the regular features of Algebra courses, and was rated accordingly. Similarly for Geometry, Proof was somewhat separate, only related to properties of polygons. Neither of these findings is surprising, as we can merely peruse the tasks assigned students in the courses to find that the vast majority of Algebra problems were symbolically-presented, while in Geometry, proofs were primarily associated with properties of triangles and their applications and not with the other, more construction-oriented, or visually-presented exercises.

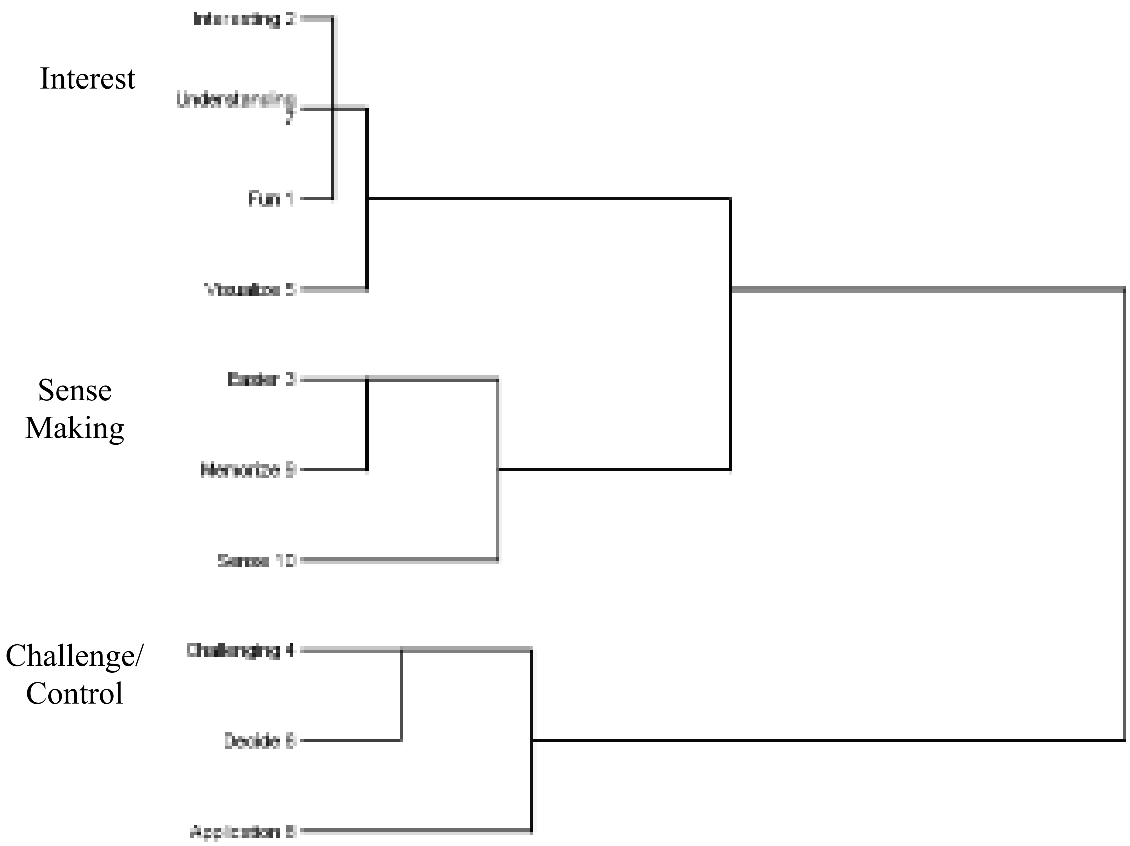

Figure 2. Organization of students' motivational constructs re: Geometry Course

Discussion

Results show that the Summer Math Academy provided an environment where students could achieve at a very high level, accelerating through Algebra and Geometry courses. Their motivation for the courses was focused on Interest, Sense-Making, and appropriate trade offs between Challenge and Control conditions. Overall, the Summer Math Academy is growing in numbers and in impact. More research needs to be conducted on how achievement is impacted, as the small numbers of students who have taken the Academy over multiple years has limited this study's ability to make longitudinal claims of impact. Nevertheless, the present study demonstrates that high challenge, motivationally relevant programs in the summer can fill an important niche in the lives of a relatively large number of students, providing enrichment and acceleration opportunities in a time that is normally educationally dormant.

COMPARING SECONDARY TEACHERS' ABILITY TO MODEL SOLUTIONS IN PROBLEM CONTEXTS INVOLVING FRACTIONS AND ALGEBRAIC STRUCTURES TO THEIR PERCEPTIONS OF THE ADEQUACY OF THEIR MODELED SOLUTIONS

Travis A. Olson
University of Nevada, Las Vegas
travis.olson@unlv.edu

Melfried Olson
University of Hawai'i at Mānoa
melfried@hawaii.edu

We build on our previous research indicating that preservice secondary teachers' encounter difficulties when attempting to model fraction problems in situational contexts where algebraic manipulations are often the expected solution method. We extend our prior research on preservice teachers by providing data gathered through investigations into the nature of in-service secondary teachers' difficulties related to similar fraction situations. Specifically, our study challenges the field to focus on the mathematical knowledge needed for teaching elementary mathematics concepts from a conceptual perspective to struggling secondary students, particularly when solution methods involving algebraic manipulations do not initially prove mathematically fruitful.

The degree to which elementary teachers struggle with conceptual understandings of fraction concepts and computation is well documented (e.g., Ma, 1999). Recently researchers have been investigating the misconceptions associated with secondary mathematics teachers and the models they create to facilitate conceptual fraction development with their students without relying on computation strategies associated with manipulating and solving algebraic expressions (e.g., Olson & Olson, 2010, 2011; Sjostrom, Olson, & Olson, 2010). This recent research offers compelling insight that preservice secondary mathematics teachers do not provide robust models for ratio and proportion situations involving fractions, nor do they accurately arrive at solutions without resorting to algebraic manipulations.

Based on our previous work and the implications thereof, the research presented in this paper represents an intentional focus on the "next steps" we previously identified to meaningfully extend our work to the examination of the ways in which *both* preservice *and* in-service secondary teachers conceive of fraction models in contextual situations. As such, the primary research question addressed in this paper is: What are secondary teachers' abilities, and perceptions of their abilities, to provide meaningful models to represent the mathematics in situated and contextualized fraction problems without explicitly relying on algebraic symbolism and manipulation?

In this paper we investigate the degree to which secondary teachers can provide a meaningful model for students lacking a robust understanding of algebraic manipulations (particularly with respect to such problems involving fractions). For our purposes, we refer to preservice and in-service teachers of Grades 7-12 as "secondary teachers." We argue that to work with students who struggle with algebra and fractions, secondary teachers must be able to provide meaningful models and representations for situations involving fractions without strictly relying on symbol manipulation and algorithmic computational strategies.

Moreover, it is our argument that the ability to present students with, and facilitate students' development of, solution methods that involve models for situations involving fractions is critical for all teachers. Such ability is specifically important for secondary mathematics teachers to effectively work with students, many of whom lack deep conceptual or computation understanding of fractions themselves. Furthermore, our study is of particular relevance to the call described in the Common Core State Standards for Mathematics ([CCSSM], 2010) Standards for Mathematical Practice for students to have the "ability to contextualize." Specifically, the second CCSSM Standard for Mathematical Practice is to, reason abstractly and quantitatively. In this standard, CCSSM authors state:

> Mathematically proficient students make sense of quantities and their relationships in problem situations. They bring two complementary abilities to bear on problems involving quantitative relationships…the ability to *contextualize*, to pause as needed during the manipulation process in order to probe into the referents for the symbols involved. Quantitative reasoning entails habits of creating a coherent representation of the problem at hand; considering the units involved; attending to the meaning of the quantities, not just how to compute then; and knowing and flexibly using different properties of operations and objects. (p. 6)

This paper extends recent research on secondary teachers fraction understandings in problem situations that allow for solutions to be both modeled (e.g., area models, pictures, number lines, and so forth) and arrived at through algebraic symbolism and manipulation. This research is significant because while researchers have examined how students and teachers understand fractional concepts (Charalambous & Pitta-Pantazi, 2007; Izak, 2008; and Sharp & Adams, 2002), Lee and Orrill (2009) indicate that most studies have not looked at teachers' knowledge any closer than simply saying that teachers' reasoning is insufficient.

Theoretical Perspectives

Lamon (2007) is widely considered the most up to date resource related to research on rational number concepts and proportional reasoning. Regarding children's understandings of fractions, Lamon states, "One of the most compelling tasks for researchers has been to discover how instruction can facilitate the joint development of rational number understanding and proportional reasoning" (p. 8). We address Lamon's idea by examining how teachers' understanding of fraction concepts in word problems involving multiplication and division situations compares to teachers' perceptions about the adequacy of their explanations of those problems. In other words, our research is positioned to understand teachers' abilities to, and perceptions of abilities to, facilitate instructional situations that foster the development of rational number understandings and proportional reasoning.

Borko, Eisenhar, Brown, Underhill, Jones, & Agard (1992) highlight certain issues underlying our research in their identification of a prospective elementary teacher with a major in mathematics who could apply and make sense of the division of fractions rule but who could not conceptually explain the situation to sixth-grade students. What we found in our previous work is consistent with NCTM (2000); the invert and multiply strategy is perhaps the most mechanical and least understood procedure in the elementary school curriculum. When looking at middle school and high school curricular topics, similar concerns should be raised about ratios and cross-multiplication. Smith (2002) reports that most students rarely use cross-multiplication. While efficient and universally applicable, students find it difficult to learn, and resist using cross-multiplication as it does not seem to match their mental operational view of ratio. Furthermore, when confronted with alternative strategies, Tirosh (2000) indicated students might consider such strategies as a type of error.

Campbell, Rowan, & Suarez (1998) argue that because algorithms are important, teachers should know and be able to use various strategies for finding a solution, and assist students in making sense of processes and procedures to determine if their work is reasonable. Related to the need for connections among algorithms and conceptual understandings related to algorithms, Ma (1999) identified Chinese elementary teachers as having a more robust understanding of the methods and techniques for comprehending and explaining concepts with fractions, especially division of fractions. Chinese teachers had a repertoire of four ways to explain division of fractions while teachers in the United States usually had only one way.

Although Ma examined elementary teachers, it is also imperative to examine secondary teachers, including ways in which their students conceive of mathematical concepts. In their work, Cramer, Wyberg, and Leavitt (2007) offer support for experiences such as those examined in our study, "Many middle school students are able to apply the algorithm for multiplying fractions, but most are unable to describe the reasons why the algorithms work. Fewer are able to make sense of the division algorithm" (p. 533). Cramer et al. further note that while middle school students are able to make connections between models, images, and symbols for addition and subtraction problems, "Developing mental images related to multiplication and division of fractions proved to be much more complex" (p. 535).

Furthermore, Kieran (2007) provides a way to conceptualize the difficulties that students have with the development of fraction concepts and computational strategies, and the connections to generating models and equations from word problems involving fractions. In particular, Kieran reports that, "Generating equations to represent the relationships found in typical word problems is well known to be an area of difficulty for algebra students" (p 271). However, there is little work done in examining how secondary students make use of modeling to solve these problems if they cannot represent the ideas with algebraic notation, including the use of ratio and proportion relationships to solve these problems.

Although the focus of Lamon's (2001) discussion is related to elementary students, we argue that many of the concerns directly relate to students of all levels, and particularly secondary students. Specifically, Lamon suggests that, "Current instruction in fractions grossly underestimates what children can do without out help. They have a tremendous capacity to create ingenious solutions when they are challenged." (p. 153) She further indicates that, "Like many constructs in mathematics, the rational numbers can be understood only in a whole system of contexts, meanings, operations, and representations." (p. 150)

Our work responds to the connections we identify that need to be made in this previous research to better understand algebra students' (or in general, secondary students') understandings of word problems involving fraction concepts and algebraic manipulations. However, more than that connection, our work responds to Son and Crespo's (2009) suggestions that it is important for the mathematics education research community to, "…continue to investigate prospective and also in-service teachers' reasoning and responses to students' thinking." (p. 259). Our work takes this line of reasoning one step farther. We ask teachers to provide an explanation to a problem, and then have them reflect on and rate the adequacy of their response to provide an explanation.

Furthermore, our research builds upon prior work examining both children's and teachers' understandings of the same fraction problem as that presented in this paper (Olson, Slovin, & Zenigami, 2009; Olson, Zenigami, & Slovin, 2008; Olson, & Olson, 2010; Olson, & Olson, 2011; Sjostrom, Olson, & Olson, 2010; Slovin, Olson, & Zenigami, 2007). In general, the investigations examined fraction word problems that have been solved by fifth-grade students with limited prior experiences related to multiplication and division of fractions, let alone the use of ratio and proportion as a solution method. Yet, these children build upon their conceptions and words in the problems to provide insightful solutions, often using linear models or number lines.

In framing strategies for solving problems, Ni (2000) discusses the use of number lines, which includes the difficulties student have in conceptually understanding the meaning and representation of a rational number. Specifically, Ni states that, "the graph representation of a given algebraic problem is not necessarily less abstract than the equation for the problem" (p. 140). However, what we have previously found is that not only do children in grades 6 - 8, find it difficult to model the solutions for these same questions, but so do secondary preservice teachers. Gilbert and Coomes (2010), in discussing a problem similar to the ones discussed in this article, offer the following argument:

> Any reasonably numerate adult should come up with an answer to this task. Teachers, however, not only must be able to answer this question correctly; the tasks of teaching require that they must also understand and interpret multiple approaches to the same answer. (p. 421)

Methodology

The same four problems used in previous studies (Olson & Olson, 2010; 2011; Sjostrom, Olson, & Olson, 2010) were used in this study, as were the same overall prompt and effectiveness rating prompts (Olson & Olson, 2010; 2011). However, only data from Problem 1 is used in this paper. The data from Problem 1 are reported for two reasons. First of all, the fifth grade children were successful in solving this problem with a process that can best be described as "an application of 1-1 correspondence." Second, for some reason, this problem often appears mysterious to teachers, especially when asked to provide an explanation. As stated, Problem 1 read: It takes 3/4 liter of paint to cover 3/5 m^2. How much paint is needed to paint 1 m^2? Explain your reasoning and support your answer.

Written instructions were provided as well as verbally given to emphasize the importance of the written work used to explain the solution process. These instructions were: For each question, show how you would explain how to solve this problem to a student who does not understand, or is having difficulty understanding, how to solve it algebraically. That is, you are to provide your solution to the problem 'according to how it is written' by using *models and sense making rather than direct computations and algebraic symbolism.*

As with prior work with these problems, Explanations were coded using the five-point explanation rubric from the State of Illinois extended response format (Illinois State Board of Education, n.d.). The complete rubric is explained in other papers (e.g., Olson & Olson, 2011), but the description of work to receive the highest rating (4) is, "Gives a complete written explanation of the solution process; clearly explains *what* was done and *why* it was done. May include a diagram with a complete explanation of all its elements." Decreasing levels of explanation (e.g., 3, 2, 1, or 0) essentially lack one or more of these components. While the explanation is consider a higher priority than only a correct answer, the answer was also rated as correct (2), incorrect (1), or no response (0). Comparing correctness of response with quality of explanation allowed us the ability to examine how well teachers could explain the problem, as well as *if* they could solve it.

After the secondary teachers had provided a solution to the problem, they were asked to rate the effectiveness of their explanation according to a five-point Likert-like scale. These data were gathered to obtain how well they felt they responded so that the explanation would be beneficial for someone who struggles with algebraic representation and symbolism. The scale for the effectiveness rating was: Highly Ineffective (1), Ineffective (2), Neither Ineffective or Effective (3), Effective (4), and Highly Effective (5).

Findings

Data were gathered from thirty-four teachers from four groups at two institutions of higher education during the 2010 – 2011 academic year. Two groups were preservice teachers and two groups were in-service teachers. For our purposes, data from the four groups were combined and are reported in Table 1.

Table 1. Individual ratings of answer, explanation and effectiveness rating

As indicated in Table 1, there were more correct answers than highest ratings for the explanations. In particular, 68% of the teachers answered correctly, but 21% did not provide an answer. Regarding the ratings for the explanations, only 32% of the teachers received a rating of 3 or 4. However, about 55% rated the effectiveness of their explanation as either a 4 or 5. Consequently, there appears to be a clear disconnect between a high quality explanation (as determined by our coding scheme), and what the *teachers* view as an effective explanation. In particular, two teachers' explanations were scored as a 1, but they rated their effectiveness as a 4 (i.e., "effective"); six teachers' explanations were scored as a 2, but they also rated their effectiveness at 4 ("effective"); and one teachers' explanation scored a 2, but this teacher rated his effectiveness at 5 (i.e., "highly effective").

We argue that these disparities are reflective of people who were able to algebraically solve the problem using an equation (or equivalence of two ratios) but they provided very little explanation beyond the equations. Certainly, the argument can be made that these teachers did not "contextualize" the fraction concepts and computations, as specifically suggested in the CCSSM. On the other hand, there were a few examples of teachers who either did not know their explanations were well presented, or otherwise displayed a lack of confidence in their explanations. Specifically, one teachers' explanation was rated 4. However, she rated her effectiveness as 2. Similarly, another teacher with an explanation rated 3, rated her effectiveness as 2. We maintain, that although these teacher's explanations were well presented, the disparity among the ratings is still indicative of a mismatch between knowing how to solve a problem and knowing if the process used will be effective in developing students' understandings.

Discussion

The results shown in this paper have many implications for teacher education. The CCSSM (2010) expects students to have computational competency, conceptual competency, and to employ standards of mathematical practices. In particular, a Grade 6 expectation for ratio and proportion is that students should be able to, "Use ratio reasoning to convert measurement units; manipulate and transform units appropriately when multiplying or dividing quantities" (p. 42). Moreover, in the notes on courses and transitions the document reads, "This body of material includes powerfully useful proficiencies such as applying ratio reasoning in real-world and mathematical problems." (p. 84.) The data from our study indicate teacher education must focus on developing teachers who can address students' understandings, particularly related to the ideas outlined in the CCSSM, namely that, "One hallmark of mathematical understanding is the ability to justify, in a way appropriate to the student's mathematical maturity, why a particular mathematical statement is true or where a mathematical rule comes from." (p. 4)

An underlying concern we identified in discussing the results of this study is the question of when do teachers gain the knowledge they need to effectively teach? More specifically, if teachers are to be prepared to model solutions to this problem for a student who does not already know, where should that teacher be expected to learn such knowledge? With an ability to make sense of the question and sketch a model, a solution can be obtained that does not depend on either complexities of division or of computations involving ratios.

Lamon (2001) states that what is needed is, "better understanding of the role that presenting and representing fractions in instruction plays in enabling or disabling the development of rational-number understanding" (p. 164). While a teacher can enable or disable the development of rational-number understanding, our study shows that our teachers' own understandings arguably were not enabled during the course of *their own* learning of rational number concepts. Consequently, these teachers will arguably not enable, nor provide the opportunity for enabling their students' development of rational-number conceptual and computational understandings.

In light of the evidence presented of secondary teachers' difficulties in modeling and explaining solutions to word problems involving fractions, as teacher educators we must ask important and timely questions of ourselves. How do we help secondary teachers learn to provide better mathematically and conceptually grounded explanations of their reasoning? How do we help secondary teachers understand if their explanations of "elementary" concepts will potentially be effective? We argue that the lack of facility to choose an effective model to represent a fraction problem involving ratios and unknown quantities will set a secondary teacher up for failure when they are faced with students who cannot reason abstractly about such problems. It is essential that secondary teachers develop multiple methods for assisting students to solve problems including the use of mathematically and conceptually rich models and multiple representations that match the context of the problems.

While these ideas can be an emphasis in teacher education coursework, we argue, like Wu (2011), that they need to be addressed in mathematics *content courses* for preservice *secondary* mathematics teachers, as well as professional development opportunities. Previously, we have stated:

> We strongly argue that the role of instruction in undergraduate mathematics classes must be adjusted to value, encourage, and emphasize deep mathematical thinking, connections, and reasoning that, along with methods courses, allow for PSSTs [Preservice Secondary Teachers] to develop more robust mathematical understandings related to facilitating the development of students' mathematical knowledge at a higher level than solely algorithmic. (Olson & Olson, 2011, p. 175)

We suggest at each phase of their professional growth, secondary teachers should be nurtured to learn the *content of mathematics* more deeply, and also be provided with experiences that enable them to develop a rich repertoire of ways to explain mathematics to students.

DEALING WITH ABSTRACTION: REDUCING ABSTRACTION IN TEACHING (RAT)

Krishna Subedi
Simon Fraser University, Canada
Kps4@sfu.ca

Reducing Abstraction in Teaching (RAT) is one of the theoretical frameworks that provide a window for looking at how teachers deal with abstraction in teaching. By analysing mathematics classroom practices captured in the public release video lessons of TIMSS 1999 through the lens of RAT, I illustrate various tendencies of teachers dealing with mathematical abstraction. I, then exemplify some instances where 'reducing abstraction' seems to be an effective teaching strategy while in other cases it may go unsupportive for the development of student's mathematical understanding.

Introduction

Abstraction is often seen as the fundamental characteristic of mathematics; it has been a central topic of discussion since the days of Aristotle and Plato. More recently, "abstraction has been recognized as one of the most important features of mathematics from a cognitive viewpoint as well as one of the main reasons for failure in mathematics learning" (Ferrari, 2003, p. 1225). As such, in the recent years, abstraction has received a growing interest in the research community among psychologists and mathematics educators. In fact, when teachers plan, one of their most important challenges is to figure out ways of translating abstract concepts into understandable ideas. If teachers understand more clearly what mental process their students go through while coping with mathematical abstraction they are attempting to teach, teachers may be able to teach more effectively and students may learn better.

Reducing Abstraction (Hazzan, 1999) is one of the theoretical frameworks that examine mental process of learners while coping with abstraction of new mathematical concepts. It has been used to examine the mental process of learners in different areas of mathematics and computer science (Raychaudhuri, 2001; Hazzan, 2002; Hazzan & Zazkis, 2005). I am however, not aware of any study that specifically looked at how teachers deal with mathematical abstraction in teaching. Hence, a question worth exploring is 'how do teachers handle the mathematical abstraction in their teaching practices? Do teachers reduce abstraction level in the first place? If yes, what is the nature of reducing abstraction?

In this paper, I first briefly visit the notion of reducing abstraction as propounded by Hazzan (1999). Second, I look at the notion of reducing abstraction from teachers' perspective rather than learners' perspective. In so doing, a new theoretical framework, which I call *Reducing Abstraction in Teaching* (RAT), has been developed. Third, using the RAT framework I analyse the mathematics classroom practices captured in the public release video lessons of TIMSS 1999. I, then exemplify some instances where reducing abstraction in teaching seems to be an effective teaching strategy, while in other cases; it may go unsupportive for the development of students' mathematical understanding. Finally, some comments and concluding remarks will follow.

Theoretical Framework

Reducing abstraction framework was first introduced by Hazzan (1999) in order to examine the mental processes of undergraduate students while learning abstract algebra. Her finding is that learners usually do not have the mental constructs or resources '*to hang on to'* to cope with the same abstraction level of the new (unfamiliar) concept and hence, they tend to reduce the level of abstraction in order to make the concept mentally accessible. This usually happens *unconsciously* (cf. Hazzan, 1999 for detailed discussion).

In this paper I, however, attempt to look at the notion of reducing abstraction in teaching. This is a shift in perspectives because a learner's goal is to learn mathematics for themselves whereas teachers are the mediators and their goals are to help their students to learn mathematics. This shift in perspective demands some modification of the original framework. For example, the choice of the words and phrases such as *'unconscious'*, '*lacks of the mental construct 'to hang on to'* are problematic in most cases. The assumption here is that teachers are the experts of the subject and they have sufficient mental resources to deal with the abstraction of the mathematics they are attempting to teach. This follows then, that the act of reducing abstraction in teaching, in most cases, are intentional and of pedagogical value. Hence, the notion of reducing abstraction in teaching is fundamentally different in its characters, goals and process from that of reducing abstraction by the learners. Hence, a modified version of the framework is required if one wants to look at the notion of reducing abstraction in teaching.

The framework of *Reducing Abstraction in Teaching* (RAT) is the result of this necessity which, I believe has "the potential to provide insight into one of the central aspects of learning mathematics and inform instructional practice" (Dreyfus & Gray, 2002, p. 113). Because of the space limitation, detailed discussion of the framework is not possible here. I, however, provide a brief overview of the RAT framework.

Reducing Abstraction in Teaching (RAT)

According to Hazzan & Zazkis (2005)*, Reducing Abstraction* refers to the tendency of the students to make sense of the unfamiliar mathematical concept by relating it to their previous knowledge and experience. This usually results in students' working in a lower level of abstraction of the concept. They maintain that all modes of students' learning can be interpreted as some way of *reducing abstraction* level.

This follows, then that while introducing new mathematical concepts, it is necessary for the teachers to maximally use the learners previously acquired knowledge, experience and level of thinking as well as their familiar contexts. In fact, as Cornu (1991) states, "for most mathematical concepts, teaching does not begin on virgin territory" (p.154), all students come with certain ideas, intuition, and knowledge already formed in their mind.

This idea is in line with many other psychologists and educators (see Piaget, 1970; Hershkowitz et al., 2001). For example, Piaget's idea of developmental psychology and genetic epistemology says that children develop abstract thinking slowly, starting as concrete thinkers with little ability to create or understand abstractions. Safuanov (2004) suggests:

> "Strict and abstract reasoning should be preceded by intuitive or heuristic considerations; construction of theories and concepts of a high level of abstraction can be properly carried out only after accumulation of sufficient supply of examples and facts at a lower level of abstraction" (p.154).

From this perspective, effective teaching should involve the process of introducing new abstractions, concretizing or semi-concretizing them, then repeating at a slightly more advanced level. That is, the concepts are concretized and presented to the students in a lower level of abstraction in order to go to the higher level of abstraction using the lower level as a stepping stone. Hence, the notion of reducing abstraction in teaching comes into play.

Building on the work of Hazzan (1999), Wilensky (1991) and Sfard (1991), three interpretations for abstraction level have been identified, all of which interpret teacher's action as some way of reducing abstraction of the concept. These three categories have been further divided into subcategories in order to incorporate different nature of the teachers' act of reducing abstraction:

Category 1: Abstraction Level as the Quality of the Relationships Between the Mathematical Concept and the Learner

On the basis of this perspective, the level of abstraction is measured by the relationship between the learners and the concept (mathematical object). It is based on Wilensky's (1991) interpretation that whether something is abstract or concrete is not an inherent property of the thing, "but rather a property of a person's relationship to an object. Concepts that were hopelessly abstract at one time can become concrete for us if we get into the 'right relationship' with them…" (p. 198). From this perspective, reducing abstraction refers to the situation where an attempt has been made to establish a *right relationship* (in the sense of Wilensky) between the students and the abstract concepts. Reducing abstraction in this category has been further divided in to three subcategories in order to incorporate different ways a teacher attempts to make unfamiliar concept more familiar to the students.

1.1) Reducing Abstraction by Connecting Mathematical Concept to Real-life Situations

Reducing abstraction in this kind refers to the situation where a teacher develops mathematical concept by connecting unfamiliar (therefore abstract) mathematical concept to the real-life situation (familiar therefore concrete). It is based on the idea that real life problems "connect better with students' intuitions about mathematics, show relevance of mathematics and provide a sense of familiarity to the students" (Hiebert et al., 2003, p. 84).

1.2) Reducing Abstraction by Using Familiar but Informal Language Rather than Formal Mathematical Language

Language plays a key role in mathematics classroom. But with regard to the use of informal language in mathematics classroom, some argue that it may give a different meaning by placing it into a different context and hence may be detrimental to formal education. Others argue that appropriate use of everyday language in mathematics teaching may be pedagogically helpful. To what extent the use of everyday language is a help or a hindrance for the learning of mathematics is debatable and is not the focus of this paper. I however, agree with Munro (1989) when he says, "Children construct new ideas and communicate these in language ... with which they are familiar,… and learn later the conventional language formats for expressing these ideas (p. 121). As such, teachers use informal everyday language in mathematics classroom before or alongside formal mathematical language with a view that use of everyday language in teaching would make the abstract concept mentally more accessible to the students thereby reducing the level of abstraction of the concept.

1.3) Reducing Abstraction by the Use of Pedagogical Tools

Reducing abstraction in this kind refers to the act of teachers in which new mathematical concept (often unfamiliar and therefore abstract) is presented to the students in fairly basic level by the use of pedagogical tools and artifacts (often familiar and therefore concrete) such as models, manipulative, metaphors, gestures, etc. These tools act as a vehicle to lead students mentally from the abstract mathematical ideas to the familiar (source) domain and then back to the realm of abstract concepts (target domain) they are attempting to teach.

Category 2: Abstraction Level as Reflection of the Process-Object Duality

Skemp (1976) introduced the idea of relational understanding and instrumental understanding in mathematics education. According to him, relational understanding involves “knowing both what to do and why” (p. 2), and “building up a conceptual structure” (p. 14). Instrumental understanding, on the other hand, shifts the focus to algorithm and end-product (answer) without any understanding. In Skemp’s words, instrumental understanding involves “rules without reasons” (p. 2) and usually can be carried out in lower level of thinking.

Along the same line, Sfard (1991) talks about the theory of process- object duality where she maintains that “abstract notation such as a number, function etc. can be conceived in two fundamentally different ways: structurally- as objects and operationally- as processes” (p 1). According to this theory, the process conception is less abstract than an object conception. In other words, the focus on procedures or the end product (answer) rather than meaningful understanding are considered to be in lower cognitive level and less abstract. The following tendencies of teacher reducing abstraction fall under this category.

2.1) Teacher Reducing Abstraction by Shifting the Focus on Procedure

Reducing abstraction in this level refers to the situation where the teacher shifts the focus on canonical procedures (how to do it) in a way that leads them away from conceptual understanding even though the original mathematical problem includes a focus on concepts, meaning, or understanding.

2.2) Reducing Abstraction by Shifting the Focus on End-product (Answer).

Reducing abstraction in this level involves the situation where the teacher shifts the focus on end-product (answer) and its accuracy even though the original mathematical problem or discussion implies a focus on concepts, meaning, or understanding.

Category 3: Degree of Complexity of Mathematical Concepts

In this category, abstraction level is determined by the degree of complexity. The working assumption here is that “the more compound an entity is, the more abstract it is (Hazzan, 1999, p. 82)”. Reducing abstraction of this kind is further divided into the following subcategories in order to incorporate the different ways of teachers act in classroom practice.

3.1) Reducing Abstraction by Shifting Focus on Particular Rather than General

Reducing abstraction in this kind refers to the situation when the presented materials and discussions limit in their meaning and scope by focusing on particular case rather than general one thus making the problem less complex for their students. Such act of teachers however provides a partial picture of the concept rather than the complete one.

3.2) Reducing Abstraction by Routinizing the Problems

Reducing abstraction in this level involves the situation where teacher takes over the challenging aspects of the problems by telling student how to solve or by solving the problem for students. In doing so, the complexity of the concepts may be reduced, but takes away the opportunities for students to discover on their own.

3.3) Reducing Abstraction by Stating the Concepts Rather than Developing It

When the concepts are involved in the lesson, they can either be developed or be stated. Reducing abstraction in this level refers to the situation when complexity of the concept or problem is reduced by stating the concept rather than developing it.

3.4) Reducing Abstraction by Giving Away the Answer in the Question (Topaze Effect)

Reducing abstraction of this kind refers to the situation when the teacher gives away the answer in the question (or provides more hint than necessary) resulting in a situation of 'Topaze effect'. The name of the 'Topaze effect' comes from a play by Marcel Pagnol written in 1928 in Paris. In the play, Topaze is a school teacher. He wants his student to succeed; be able to find an answer of the problem by the student himself. When the student cannot find the answer easily, the teacher gives away the answer within the question itself in a slightly indirect way thereby lowering the intellectual demandingness of the tasks (cf. Brousseau, 1997). Later the student produces the correct answer but without having learned anything. This is what Brousseau (1997) calls 'Topaze effect'.

I want the reader to note that these three categories of abstraction should not be thought of as hierarchical or disjointed, they are rather intersecting, or one may even emerge from the other. For example, a teacher trying to deal with a concept in a less complex manner (category 3) or a shift of focus to procedures (category 2) can be interpreted as an attempt of the teacher to make the concept more familiar (category 1) for their students. So, based on the perspectives one takes, one category of reducing abstraction can be thought of as reducing abstraction in the other category. I, therefore, assign the teacher's act of reducing abstraction to the categories that I deem they fit best.

Methodology

The research questions that guided this work are: 1) how do teachers deal with abstraction in mathematics teaching? 2) Can the Reducing Abstraction in Teaching (RAT) framework suggest a plausible explanation for the action of teachers and sources of teaching activities? 3) What are the impacts on student's understandings or misunderstanding of the concept due to the act of reducing abstraction in teaching? In this paper, I however, focus on the first two questions, leaving the third one for the future project. For the purpose of this paper, I used TIMSS 1999 public release video lessons to gather the data.

TIMMS 1999 video study was conducted by LessonLab, Inc. under contract to the U.S. Department of Education (Hiebert et al., 2003). The study involved 638 eighth-grade mathematics lessons that were selected randomly to be the representative of teaching in the seven participating countries- USA, Australia, the Czech Republic, Hong Kong, Japan, the Netherlands, and Switzerland. The videos were analysed by TIMMS videos study team itself and others using different theoretical frameworks (Hiebert et al., 2003) with a focus on various aspects of teaching and learning. I am however, not aware of any study with its focus on teachers' dealing with abstraction in teaching. Hence, my present study took place.

My analysis was based on transcripts of the public release video lessons that have been translated into English by TIMMS 1999 video study team. Public release video lessons consist of four lessons from each of the seven participating countries. I read the transcripts repeatedly with an eye towards identifying key teachers' actions and searching and developing the meaning for each of their action. For lesson from English speaking countries, I also watched videos repeatedly. Because of the dynamic nature of video, they were very helpful in my attempt to understand what is going on in the classroom that might otherwise be impossible to see (from the transcript only).

Results and Discussion

Because of the space limitation, I provide examples and discussion on some of the categories and subcategories only.

Category 1: Abstraction Level as the Quality of the Relationships Between the Mathematical Concept and the Learner

Example 1

Consider the following example:

00:04:33	T	We know that the edges of a triangle- or any figure- are called "sides".
00:04:38	T	In a right-angled triangle, this side is attached to a right angle. So what should we call this side? A right-angled side.
00:04:47	T	Yes? Because this side is attached to a right angle so you call that a right-angled side.
00:05:00	T	Do we have any other right-angled side in there?
00:05:02	SN	Yes.
00:05:03	T	Yes, all the way on the other side. That one is attached to the right angle as well, therefore you call that a right-angled side as well.
00:05:19	T	Then I still have one side left. It isn't so obvious because it is lying flat. But if you see this triangle, what can we call that side?
00:05:28	SN	The long side.
00:05:29	T	The long side. That is correct. Or in a different way?
00:05:33	SN	The right side?
00:05:34	T	It is actually at an angle. If you see it in such an- like a diagonal- so you call this the sloped side or the hypotenuse, is what you call this one.
00:05:45	T	These are just names, you know, you may also keep calling this "the long side", no problem. (NTL-PRL 02)

Here, the teacher uses words from everyday language such as ‘the side lying flat” ‘the long side’, side ‘like a diagonal’ and ‘sloped side’ to represent hypotenuse. The use of such informal, kid- friendly language to introduce the concept is an attempt on the teacher’s part to make the unfamiliar (abstract) concept more familiar to the students thereby reducing the level of abstraction of the concept (Category 1.2).

Example 2

Teacher assign the task of solving equation 4x = 4x -1.

00:38:57	T	what do we have that's tricky? We have four X is equal to four X... minus one. So how are we going to see that?
00:39:04	SS	It's not possible!
00:39:09	T	It's impossible. Valentine?
00:39:11	SN	Because it need a place, for example four X is equal to three X minus one. Otherwise we can't take away the X's. We can't take away one.
00:39:21	T	Let's try to take it away, let's try to be as methodical as we can, then let's see what happens. Let's see, what do we find, so-

Dialogue continues…

00:39:35	T	Therefore zero is equal to minus one. Is that possible?
00:39:42	SS	No!

00:39:43 T No. Therefore when you get to a case like this...

At this stage, some of the students seem to be struggling to make sense of what it means when they get 0 = -1 while solving the equation. At this time, the teacher refers to the graphical method in which case students saw clearly that the lines are parallel and so there is no point of intersection. That is, there is no solution. The dialogue continues:

00:41:33 S It is parallel.
00:41:33 T It is, well, parallel. Therefore when do they meet each other, lines?
00:41:37 SS Never.
00:41:37 T Never. Therefore the- what we're looking for as a solution, it's the points that meet each other. Therefore there's none.

Teachers act of mapping the unfamiliar (solution of equations as a null set) target domain to the students familiar source domain (visual representation of the parallel lines) in order to make the concept mentally accessible can be interpreted as an act of reducing abstraction in by the use of pedagogical tools (Category 1.3).

Category 2: Abstraction Level as Reflection of the Process-Object Duality

Example 3

Following dialogue from an Australian lesson illustrates the behavior of reducing abstraction in this category.

00:00:34 T All right, this one is A B C, and this one is D E and F. All right, they are congruent. So I'm going to ask you- ask you 10 quick questions on that.
00:00:49 T All right, number one, which angle is equal to angle A?
00:01:04 T Which angle is equal to angle D?
00:01:15 T Number three, if angle A is 30... and angle D is 60... uh, what size is angle E?
00:01:35 T And number four, what size is angle D?
00:01:49 T Which line is equal to B C?

Teacher continues asking all 10 product questions that do not require any explanation.

00:04:25 SN And 10 is A B.
00:04:26 SN Why?
00:04:28 T Ten is A B. Just to show the congruence show relationship between them…
00:04:33 T Who got them all right? That's pretty good. Who got nine right?
00:04:40 SN Yeah I did.
00:04:42 T Yeah, right. Number 10 was A B…
00:04:46 T All right, okay, I've got a worksheet for you to do... *(AU-PRL2)*

The original problem could lead to the discussion about congruent triangles that might push them to learning with understanding, but the teacher opted to focus on the answer rather than clarifications and justifications from the students. This act can be interpreted as reducing abstraction by shifting the focus on end-product or answer (Category 2.2)

Category 3: Abstraction Level as Degree of Complexity of Mathematical Problem/Concept

Example 4

Consider the following dialogue that focuses on the concept polygon and its interior angles.

00:06:40 T Okay, what are the differences between convex and concave polygon?
00:06:45 T We look at the concave polygon. At least- at least one or more of the interior angles is greater than 180 degrees.

00:06:56 T	We call this concave polygon. Understand?
00:06:59 T	But in this chapter, we don't discuss the concave polygon; we just only discuss the convex polygon. Okay? … *[Dailogue continues.]*
00:07:15 T	Sorry. It is uh, uh, you have learned it in Form One. It is the... equilateral polygon and also... equiangular polygon.
00:07:32 T	What is meant by equiangular polygon? And equilateral polygon?
00:07:58 T	Equilateral polygon? Do you still remember it?
00:08:02 S?	Yes.
00:08:03 T	what does it mean? I'll give you some hints. All the sides..?
00:08:10 SN	Are equal.
00:08:10 T	All the sides are equal. Okay? All the sides of the polygons are equal.
00:08:16 T	How about equiangular polygon?
00:08:17 SS	(inaudible)
00:08:18 T	All the sizes of the angle…?
00:08:21 SN	Are equal.
00:08:21 T	Equal. Get it? *(HK – PRL3)*

At 6:40, and at 7:32, teacher seems to open up the dialogue on the concept of concave and convex polygon, and equilateral and equiangular polygon respectively. He however, took over the challenging aspects and complexity of the problem by telling them the meaning of concave polygon at 6:45. This act of teacher can be interpreted as reducing abstraction by routinizing. *(Category 3.2).*

Further, at 8:03 the teacher asks the question about equilateral polygon and at 8:18 about equiangular polygon. However, teacher choice of questions such as equilateral polygon means, "all the sides are ?"… and equiangular polygon means, "all the angles are?", actually contain the answers within the questions in a slightly disguise form. This type of question in teaching may reduce the complexity of the problem for the students and that students may be able to produce correct answer, it however does not lead students to learning with understanding. (Topaze effect-c*ategory 3.4)*.

Conclusion

In this paper, my aim was to explore how teachers deal with mathematical abstraction in teaching. Do teachers reduce abstraction level in the first place? If yes, what is the nature of reducing abstraction in teaching? In order to answer these questions, a new theoretical framework, which I call Reducing Abstraction in Teaching (RAT), has been developed. Using the RAT framework, I analysed some of the classroom practices captured in the TIMMS 1999 public release video lessons. I found it helpful to use RAT framework to explore the actions of teachers and sources of teaching activities in regard to dealing with mathematical abstraction in teaching. I identified various tendencies of teacher reducing abstraction in teaching, which I summarized under three main categories and subcategories.
